**Appendix L.      Health and Safety Risks from  
Increased Glyphosate and Other  
Chemical Usage on Humans  
(Exclusive of Field Workers)**

# **Health and Safety Risks from Increased Glyphosate and Other Chemical Usage on Humans (Exclusive of Field Workers)**

## **Executive Summary**

In an effort to assess the potential health and safety risks from increased glyphosate and other chemical usage on humans (exclusive of field workers) due to the deregulation of glyphosate-tolerant alfalfa by the U.S. Department of Agriculture (USDA) in 2005, a human health risk and safety assessment was conducted for glyphosate usage on glyphosate-tolerant (GT) alfalfa. Conservative hazard estimates suggest that the majority of the population is not at risk for adverse health effects associated with acute exposure to glyphosate. Based on upper estimates of exposure, however, infants consuming fruit and all age groups consuming vegetables may be at risk for adverse effects associated with acute exposure to glyphosate. More details on the toxicity and risk of glyphosate are discussed in this technical report.

Glyphosate is a broad spectrum herbicide. It is a systemic, post-emergence herbicide widely used on agricultural commodities (food uses) and non-agriculture sites. Glyphosate absorbs directly through plant leaves and rapidly spreads throughout the plant. The use of surfactants enables greater leaf penetration. Glyphosate's mode of action is as a potent and specific inhibitor of the enzyme, 5-enolpyruvylshikimate 3-phosphate synthase. This enzyme is located in the shikimate pathway and is essential for the biosynthesis of aromatic amino acids and other aromatic compounds in algae, higher plants, bacteria, fungi, and apicomplexan parasites. The shikimate pathway is absent in mammals.

Glyphosate is among the most widely used pesticides by volume in the United States and other glyphosate products are available; however, use data for GT alfalfa were only found for Monsanto products. The only products approved and that have a subsequent proposed maximum use rate for GT alfalfa are the following Monsanto glyphosate herbicide products: Honcho, Honcho Plus, Roundup Original MAX, Roundup WeatherMAX, and Roundup Ultra MAX II. Glyphosate products can be formulated to have different concentrations of glyphosate acid per gallon of product. To improve handling, performance, and concentration, the glyphosate acid is formulated as a salt compound. The term acid equivalent (a.e.) refers to the weight of the glyphosate acid, which is herbicidally active, while the term active ingredient (a.i.) is the weight of the glyphosate acid plus the salt. It is best to refer to a.e. when comparing glyphosate products and rates.

The United States Environmental Protection Agency (US EPA) and the states (usually the state's agriculture office) are responsible for registering or licensing pesticides for use in the United States. US EPA receives its authority to register pesticides under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA). Glyphosate was registered as an herbicide pesticide within the United States through the US EPA. The US EPA's toxicological database on

glyphosate is considered adequate and complete (US EPA, 2006; 1993), and based on this data, glyphosate is considered to be a toxicologically low-risk herbicide (Cerdeira and Duke, 2006). According to the Reregistration Eligibility Decision document for glyphosate (US EPA, 1993), glyphosate is of relatively low oral and dermal acute toxicity. For this reason, glyphosate has been assigned to Toxicity Categories III and IV for these effects (i.e., Toxicity Category I indicates the highest degree of acute toxicity, and Category IV the lowest). Furthermore, an acute inhalation study was waived by the US EPA because glyphosate is a non-volatile solid and the studies conducted on the end-use product formulation are considered sufficient. In terms of subchronic and chronic toxicity, one of the more consistent effects of exposure to glyphosate is loss of body weight. This observed weight loss may be consistent with experimental data indicating glyphosate's mechanism of action. Other general and non-specific signs of toxicity from subchronic and chronic exposure to glyphosate include changes in liver weight, blood chemistry (may suggest mild liver toxicity), liver pathology, and pituitary weight (USDA, 2003). Glyphosate is not considered a carcinogen; it has been classified by the US EPA as a Group E carcinogen (evidence of non-carcinogenicity for humans) (US EPA, 2006; 1993).

The general public may be exposed to herbicides used on glyphosate-tolerant (GT) alfalfa if they consume crops that were grown near GT alfalfa fields. Acute oral exposure estimates from fruit ingestion for adults ranged from zero to 1.25 mg/kg body weight per day. For elderly people, acute oral exposure estimates from fruit ingestion ranged from 0.0125 to 0.45 mg/kg body weight per day. For infants, acute oral exposure estimates from fruit ingestion ranged from zero to 6.32 mg/kg bodyweight per day. Acute oral exposure estimates from vegetable ingestion for adults ranged from 0.185 to 4.61 mg/kg body weight per day. For elderly people, acute oral exposure estimates from vegetable ingestion ranged from 0.222 to 5.11 mg/kg body weight per day. For infants, acute oral exposure estimates from vegetable ingestion ranged from 0 to 12.1 mg/kg body weight per day.

Central and lower hazard quotient (HQ) estimates were all under 1, suggesting that the majority of the population is not at risk of adverse health effects associated with acute exposure to glyphosate. Based on upper estimates of exposure, however, infants consuming fruit and all age groups consuming vegetables may be at risk of adverse effects associated with acute exposure to glyphosate. The age group at highest risk is infants under one year of age, which is consistent with US EPA's findings (US EPA, 2006; 1993). The upper estimate HQ for infants with acute exposure to fruit was approximately 3. The upper estimate HQs for all age groups with acute exposure to vegetables ranged from approximately 2 to 6. These results are all over 1, suggesting the potential for adverse health effects associated with glyphosate. It should be noted, though, that the upper estimates of risk are based on highly conservative fruit and vegetable intake rates; thus it is anticipated that only a very small number of individuals will have this magnitude of exposure and therefore be at this level of risk.

Chronic oral exposure estimates from fruit ingestion for adults ranged from 0 to 0.683 mg/kg body weight per day. For elderly people, chronic oral exposure estimates from fruit ingestion ranged from 0.00682 to 0.246 mg/kg body weight per day. For infants, chronic oral exposure estimates from fruit ingestion ranged from 0 to 3.46 mg/kg body weight per day. Chronic oral exposure estimates from vegetable ingestion for adults ranged from 0.101 to 2.52 mg/kg body weight per day. For elderly people, chronic oral exposure estimates from vegetable ingestion

ranged from 0.122 to 2.80 mg/kg body weight per day. For infants, chronic oral exposure estimates from vegetable ingestion ranged from zero to 6.65 mg/kg body weight per day.

Central and lower HQ estimates were all under 1, suggesting that the majority of the population is not at risk of adverse health effects associated with chronic exposure to glyphosate. Based on upper estimates of exposure, however, infants consuming fruit and all age groups consuming vegetables may be at risk of adverse effects associated with chronic exposure to glyphosate. The age group at highest risk is infants under one year of age, which is consistent with US EPA's findings (1993, 2006). The upper estimate HQ for infants with chronic exposure to fruit was approximately 2. The upper estimate HQs for all age groups with chronic exposure to vegetables ranged from approximately 1 to 3. These results are all greater than or equal to one, suggesting the potential for adverse health effects associated with glyphosate. It should be noted, though, that the upper estimates of risk are based on highly conservative fruit and vegetable intake rates; thus it is anticipated that only a very small number of individuals will have this magnitude of exposure and, therefore, be at this level of risk.

## 1.0 Introduction

### 1.1 Background

In June 2005, the United States Department of Agriculture (USDA) approved the use of Roundup Ready® alfalfa, the only commercially available genetically engineered alfalfa on the market. The Monsanto Company (Monsanto) produced this glyphosate tolerant (GT) alfalfa variety in partnership with the largest alfalfa seed company, Forage Genetics International. This genetically engineered alfalfa is resistant to the herbicide glyphosate (i.e., the alfalfa is able to survive applications of the herbicides containing glyphosate), the active ingredient in the Monsanto Company's trademark herbicide, Roundup®. The transgene responsible for glyphosate resistance was first introduced in soybeans in 1996, and has been commercialized in several other crops (e.g., corn, canola, and cotton) since then. Alfalfa is the first perennial GT crop that was approved for commercial planting in the United States. In 2005 when GT alfalfa was introduced commercially, only 0.2% of the total harvested alfalfa was GT alfalfa; however, in 2006, three million pounds of seed was made available for planting (Gianessi and Reigner, 2006).

Glyphosate was first introduced as an herbicide under the trade name of Roundup by Monsanto in 1974. Glyphosate is a non-selective herbicide registered for use on many food and non-food field crops as well as non-crop areas where total vegetation control is desired. Glyphosate is among the most widely used pesticides by volume (US EPA, 1993). Glyphosate use increased more than six-fold between 1992 and 2002, to become the most used herbicide in the United States, in most part due to approval of several GT crops (Gianessi and Reigner, 2006). In 1997, it was listed on the Agency of Toxic Substances and Disease Registry's (ATSDR) 100 most frequently released substances (ATSDR, 1997).

A controversy exists over whether glyphosate usage has increased as a result of GT crops. A few studies have claimed that the volume of herbicide use is greater due to GT crops (Benbrook, 2004; 2003; 2001). On the other hand, others, such as Heimlich et al. (2000) have indicated there has not been a significant increase in the amount of glyphosate usage since emergence of GT crops. Heimlich et al. (2000) noted that using glyphosate has resulted in the replacement of herbicides that are at least three times as toxic and persist almost twice as long as glyphosate. For example, in cotton and soybeans fields, for the most part, several herbicides were replaced by glyphosate (million pounds reduction): bentazon (-4.4), disodium methanearsenate (DSMA; -0.8), fluometuron (-4.5), imazethapyr (-1.0), metribuzin (-1.5), methylarsonic acid sodium salt (MSMA) (-1.7), paraquat (-2.9), pendimethalin (-14.0), sethoxydim (-1.1), and trifluralin (-13.0). Furthermore, prior to 2002, metolachlor, which accounted for 67 million pounds of herbicide used in 1997, was voluntarily withdrawn from the market prior to 2002; R/S Metolachlor was voluntarily cancelled, but S-Metolachlor replaced it on the market. Glyphosate was adopted on many soybean acres that were previously treated with metolachlor. Cyanazine, which accounted for 20 million pounds of herbicide used in 1997, was also voluntarily withdrawn from the market prior to 2002 and replaced by glyphosate for use on cotton and corn. In addition to glyphosate, corn producers replaced cyanazine with the herbicides mesotrione, rimsulfuron, and simazine (Gianessi and Reigner, 2006).

Additionally, Trewavas and Leaver (2001) conducted an analysis which revealed that 3.27 million kg of other herbicides have been replaced with 2.45 million kg of glyphosate in soybean fields in the U.S. Carpenter and Gianessi (2003) concluded that the introduction of GT soybeans has resulted in a decrease in the total volume of herbicides used. Gianessi (2005) estimates that averaged over all GT crops, GT technology has reduced herbicide use by 17 million kg/year in the U.S. However, Gianessi's (2005) calculations indicate that if GT sugarbeets were adopted, reduction in herbicide use would not be as great as for combined GT crops, because the herbicides used now in non-transgenic sugarbeets are mainly low use rate compounds in the U.S.

## 1.2 Methodology

In the preparation of this human health risk assessment, literature searches of glyphosate toxicity and exposure were conducted in the open literature using the literature search strategy presented in appendix L-2 of this technical report. This human health risk assessment is not a comprehensive summary of all of the available information and does not cite all of the available literature. As USDA determined in 2003, an all inclusive and detailed review of each study would tend to obscure rather than inform. Therefore this document relies on the information that is likely to impact the risk assessment. Primary sources of data were obtained from the following three documents: the United States Environmental Protection Agency (US EPA) 1993 Reregistration Eligibility Decision (RED) document on glyphosate (US EPA, 1993); the U.S. EPA's Glyphosate Human Health Risk Assessment for Proposed Use on Indian Mulberry and Amended Use on Pea, Dry (US EPA, 2006); and the USDA, Forest Service 2003 human health and ecological risk assessment on glyphosate (USDA, 2003). However, several DIALOG databases were searched, and Google, and Google Scholar search engines supplemented the DIALOG search. References were selected from the extensive list of literature based on requesting the abstracts and determining if the open literature data were not included in the three primary documents listed below or provided contrary or controversial information to these documents.

Additionally, for the exposure assessment, the application rate of glyphosate on GT alfalfa was determined by reviewing the five glyphosate herbicide formulations that are labeled for use on GT alfalfa and report the maximum daily and yearly use rate on GT alfalfa. These formulations are all Monsanto Company products, as GT alfalfa is also a Monsanto product. To develop the quantitative risk assessment the maximum use rate was determined to be 1.99 lb a.e./acre for a single use (rounded to 2 lb a.e./acre in calculations), with minimum reapplication within seven days and not to exceed 7.98 lb a.e./acre in a year. The maximum label rate for a single ground use of Roundup® products used on GT alfalfa is 1.55 lb a.e./acre. Thus, the risk assessment is a conservative one. Furthermore, it should be noted that in this technical report, the term a.e. refers to the weight of the glyphosate acid, which is herbicidally active, while the term active ingredient (a.i.) is the weight of the glyphosate acid plus the salt.

## 2.0 Overview of Glyphosate

### 2.1 Glyphosate

Glyphosate is a systemic, post-emergence herbicide widely used on agricultural commodities (food uses) and non-agriculture sites. Glyphosate salts serve as the source of *N*-(phosphonomethyl)glycine. Several salts of glyphosate with different counter cations are currently marketed. Each salt has a different “glyphosate equivalent”, which is defined as the ratio of the molecular weight of *N*-(phosphonomethyl)-glycine to the molecular weight of the salt. While GT alfalfa could tolerate other herbicides formulated with glyphosate, there are only certain glyphosate herbicides approved for use on GT alfalfa. The five currently approved glyphosate-containing herbicides are presented in table L-1. For the remainder of this report, these products will be referred to simply as glyphosate formulations.

**Table L-1. End Use Products Approved for Use on Glyphosate-Tolerant Alfalfa**

#### *Structure and Nomenclature*

Glyphosate is a substituted glycine, the simplest amino acid. The glyphosate molecule has a methylphosphono group bonded to the nitrogen atom of the amino group of glycine as denoted in figure L-1 below.

**Figure L-1: Glyphosate molecular structure**

Glyphosate's structure and nomenclature are presented in table L-2 below.

**Table L-2. Glyphosate Structure and Nomenclature**

| Property                                               | Value                                           | Source             |

## 2.2 Summary of Findings

Glyphosate is a systemic, post-emergence herbicide widely used on agricultural commodities (food uses) and non-agriculture sites. Glyphosate salts serve as the source of *N*-(phosphonomethyl)glycine. Several salts of glyphosate with different counter cations are currently marketed. At ambient temperatures, glyphosate is a white crystalline substance that is not volatile with high water solubility. In the crystalline form, glyphosate has both positive and negative regions of charge these dipolar ion species are sometimes referred to as a zwitterion. In aqueous solutions, the hydrogen atoms of the carboxylic acid (COOH) and phosphate (PO<sub>2</sub>H<sub>2</sub>) groups may be associated or dissociated depending on the pH of the solution. These dipolar ion species are the regions expected to bond to carbon containing molecules in the soil. Glyphosate is in a liquid form for herbicide formulations; generally, the composition of the herbicide is considered a trade secret. One formulation of glyphosate, Honcho®, has a tallow amine surfactant (Monsanto, 2007a). This and other surfactants are added to the herbicide formulations to increase leaf penetration.

## 3.0 Human Health Risk Assessment

### 3.1 Hazard Identification

This general public risk assessment focuses on risks associated with exposure to herbicides recommended for use on GT alfalfa, all of which contain the active ingredient glyphosate. The risk assessment is presented in four sections including a hazard identification section in which toxicological data on glyphosate are reviewed and summarized, an exposure assessment section, in which exposure estimates for the general public are presented, a dose-response assessment section, in which health benchmarks for glyphosate are reviewed and recommended for different exposure scenarios, and, finally, a risk characterization section, in which worker exposure estimates are compared to health benchmarks to determine the potential for adverse health effects associated with general exposures to glyphosate.

#### 3.1.1 Overview

According to the US EPA, the existing toxicity database for glyphosate is complete and without data gaps. There is high confidence in the quality of the existing studies and the reliability of the toxicity endpoints identified for use in risk assessment (US EPA, 2006; 1993). In general, the herbicidal activity of glyphosate is due primarily to a metabolic pathway that does not occur in humans or other animals, and, thus, this mechanism of action is not directly relevant to the human health risk assessment. However, little has been elucidated regarding glyphosate's mechanism of action in humans or experimental animals. Nonetheless, the US EPA considers glyphosate to be of low acute toxicity by oral, dermal, and ocular routes of exposure, since all studies are classified as Toxicity Category III (slightly toxic) or IV (practically non-toxic). Furthermore, an acute inhalation study was waived by the US EPA because glyphosate is a non-volatile solid and the studies conducted on its end-use product (EUP) formulations are considered sufficient (US EPA, 2006; 1993).

In terms of subchronic and chronic toxicity, one of the more consistent effects of exposure to glyphosate is loss of body weight. This observed weight loss may be consistent with experimental data indicating glyphosate's mechanism of action as an uncoupler of oxidative phosphorylation (see section 3.1.2). Other general and non-specific signs of toxicity from subchronic and chronic exposure to glyphosate include changes in liver weight, blood chemistry (may suggest mild liver toxicity), liver pathology, and in pituitary weight (USDA, 2003). Glyphosate is not a carcinogen, however, and has been classified by the US EPA as a Group E carcinogen (evidence of non-carcinogenicity for humans) (US EPA, 2006; 1993). Glyphosate's toxicity database and its mechanism of action are discussed in greater detail in the following sections. Additionally, a summary table of the toxicology studies included in the USDA (2003) and US EPA (1993) documents is included in appendix L-3 of this technical report.

### 3.1.2 Mechanisms of Action

In plants, glyphosate is a potent and specific inhibitor of the enzyme 5-enolpyruvylshikimate 3-phosphate synthase (EPSPS) in plants. EPSPS is the sixth enzyme on the shikimate pathway and it is essential for the biosynthesis of aromatic amino acids and other aromatic compounds in algae, higher plants, bacteria, fungi, and apicomplexan parasites. However, this metabolic pathway does not exist in humans or other animals (USDA, 2003; US EPA 1993).

While its mechanism of action in plants is well understood, not much is known about glyphosate's ability to cause toxic effects in humans or experimental animals. Corrosive effects on the gastric mucosa, as well as other tissues, are a consistent response following acute oral exposure to high doses of glyphosate or polyethoxylated tallow amine (POEA), a surfactant included in some glyphosate formulations. However, it is speculated that the biochemical pathway leading to mucosal effects differs for each glyphosate and POEA. At present, there are two proposed biochemical mechanisms of action in humans for glyphosate: uncoupling of oxidative phosphorylation and inhibition of hepatic mixed function oxidases (USDA, 2003).

Oxidative phosphorylation is a process where nutrients are oxidized to yield metabolic energy which is then transferred to high-energy phosphate bonds and stored. Glyphosate appears to be an uncoupler of oxidative phosphorylation based on the results of a series of experiments using rat liver mitochondria that was exposed to glyphosate (USDA, 2003). When glyphosate uncouples this process, the result is a loss of energy and eventually death. Symptoms such as increased heart and respiratory rate, labored breathing, profuse sweating, fever, metabolic acidosis, and weight loss may occur in response to the uncoupling of oxidative phosphorylation. Uncoupling of the oxidative phosphorylation process has been seen after experimental animals were given intraperitoneal doses as low as 15 mg/kg. However, it has not been determined if uncoupling of oxidative phosphorylation plays a major role in acute exposures (USDA, 2003).

Inhibition of hepatic mixed-function oxidases may also account for some of the toxic effects observed following glyphosate exposure. Hepatic mixed-function enzymes are comprised of various isozymes of cytochrome P-450, which is involved in the metabolism of a variety of endogenous compounds as well as xenobiotics. In a study by Hietanen et al. (1983), a decrease in hepatic mixed-function oxidase activity was observed in rats after a 500 mg/kg/day dose of glyphosate for four days followed by doses of 300 mg/kg/day for six days. While, this decrease in hepatic mixed-function oxidase activity is only indicative of cytochrome P-450 inhibition, it has been suggested that this effect may be due to glyphosate's inhibition of cytochrome P-450, since glyphosate has caused inhibition in plants (USDA, 2003).

### 3.1.3 Kinetics and Metabolism

The residue of concern for risk assessment purposes is glyphosate *per se*. Glyphosate's only known metabolite, aminomethylphosphonate (AMPA; see figure L-2), is not included in either the tolerance expression or the risk assessment (US EPA, 2006). While AMPA is a common environmental metabolite, only trace amounts of it are formed in mammals, with the remainder being excreted unchanged. For this reason, direct exposures to AMPA, as an endogenous metabolite in animals, are encompassed by the existing toxicity data on glyphosate.

**Figure L-2: Chemical structure of AMPA**

Since glyphosate is rapidly eliminated from the body and shows a lack of degradation into toxic metabolites, dose levels expressed in mg/kg/day display analogous effects over broad periods of exposure (USDA, 2003). For the general public, the majority of exposures to glyphosate are via the oral and dermal route. Select results from both oral and dermal absorption studies are discussed below.

According to experimental studies, glyphosate is not completely absorbed following oral administration. Much of the reviewed literature has revealed that only about 30% of glyphosate is absorbed from the gastrointestinal tract after oral exposure (USDA, 2003). One metabolism study available at the time of the 1993 reregistration of glyphosate involved a single or repeated dose of radiolabeled  $^{14}\text{C}$ -glyphosate administered orally to Sprague-Dawley rats. Of this dose, 30-36% was absorbed, <0.27% was eliminated as  $\text{CO}_2$ , 97.5% was excreted in the urine and feces as parent compound, and 0.4-0.7% was excreted in the urine and feces as AMPA. Repeated dosing did not significantly change the metabolism (US EPA, 1993).

Furthermore, studies conducted by Davies (1996e), indicate that the majority of unabsorbed glyphosate remains in the gastrointestinal tract, while the absorbed glyphosate is widely distributed throughout the body. The highest concentrations of glyphosate are found in the bone relative to other tissues, although glyphosate does not significantly concentrate or persist in any tissue (US EPA, 1993). A second metabolism study available at the time of the 1993 reregistration of glyphosate involved dosing Sprague-Dawley rats with a single 1150 mg/kg intraperitoneal injection of radiolabeled  $^{14}\text{C}$ -glyphosate. Approximately 0.0044-0.0072% of this dose was found in the bone marrow after 30 minutes. The half-life of glyphosate in bone marrow was 7.6 hours for males and 4.2 hours for females. In addition, the study determined that the half life of glyphosate in plasma was 1 hour for both sexes (US EPA, 1993).

Glyphosate is also poorly absorbed following dermal applications. Two dermal absorption studies performed by Wester et al. (1991; 1996) indicate that glyphosate is poorly absorbed

across the skin. One of the studies was performed using skin from human cadavers. In this study, the cadaver skin was exposed to an undiluted glyphosate herbicide formulation (i.e., Roundup) for eight hours and diluted formulations (i.e., 1:20 and 1:32 dilutions of Roundup) for up to 16 hours. In general, formulations generally contain more of the POEA surfactant than the active ingredient, glyphosate. Based on 16-hours of exposure to the diluted formulations, first-order dermal absorption rates ranged from  $1.3 \times 10^{-4}$  to  $1.0 \times 10^{-3} \text{ h}^{-1}$  (average:  $4.1 \times 10^{-4} \text{ h}^{-1}$ ), while first-order dermal absorption rates after 8-hours of exposure to the more concentrated formulation ranged from  $7.5 \times 10^{-5}$  to  $5.1 \times 10^{-4}$  (USDA, 2003). The results of this study indicated that glyphosate containing more of the POEA surfactant (i.e., the undiluted formulation) did not absorb more rapidly than a glyphosate formulation with a less concentrated solution of surfactant. A second study was performed on monkeys and found that after 12 hours of exposure approximately 1.5% of the glyphosate was absorbed in 12 hours, which is equivalent to a first-order dermal absorption rate of  $1.3 \times 10^{-3} \text{ hour}^{-1}$  (Wester, 1991). These experimental measurements and methods are consistent with other derived values and standard methods used to estimate first-order dermal absorption rates (USDA, 2003)

### *3.1.4 Acute Systemic Toxicology*

As is common with most chemicals, acute exposure to glyphosate and its commercial formulation may be toxic at sufficiently high levels. For example, an experiment performed by Williams et al. (2000) on rats and mice found that acute oral LD<sub>50</sub> values (the lethal dosage required to kill 50 percent of a population of test animals) of glyphosate range from approximately 2,000 to 6,000 mg/kg and acute oral intraperitoneal LD<sub>50</sub> values, which are about 10 times lower in value, range from 134 to 234 mg/kg (USDA, 2003). Additionally, systemic differences in toxicity do not appear to exist among species when doses of glyphosate are expressed in units of mg/kg body weight.

Documentation suggests that exposure to glyphosate with a POEA surfactant is a common means of suicide, and this fact can be used to make a determination about its effects on humans. In an analysis of suicide cases in Taiwan, doses of glyphosate/surfactant formulations in the range of  $330 \pm 42 \text{ mL}$  were associated with fatalities and the survivors were correlated with doses of  $122 \pm 12 \text{ mL}$ . Gastrointestinal effects (vomiting, abdominal pain, diarrhea), irritation, congestion, or other forms of damage to the respiratory tract, pulmonary edema, decreased urinary output sometimes accompanied by acute renal tubular necrosis, hypotension, metabolic acidosis, and electrolyte imbalances, probably secondary to the gastrointestinal and renal effects, are seen in human cases of glyphosate/surfactant exposure. It is speculated that the POEA surfactant component in the glyphosate formulations may be the dominant contributing factor leading to the effects seen in these suicide cases (USDA, 2003).

In terms of this risk assessment, however, only the increased use of glyphosate as an herbicide is being considered. According to the US EPA, glyphosate is considered to be of low acute toxicity by oral, dermal, and ocular routes of exposure, since all studies are in Toxicity Category III or IV, considered slightly to practically non-toxic, respectively. Furthermore, an acute inhalation study was waived by the U.S. EPA because glyphosate is a non-volatile solid and the studies conducted on the end-use product formulation are considered sufficient (US EPA, 2006; 1993). Additionally, according to the World Health Organization (WHO), glyphosate has been

classified as unlikely to present an acute hazard in normal use (WHO, 1996). The US EPA's acute toxicity profile for glyphosate is presented in table L-4.

**Table L-4. Acute Toxicity Profile of Glyphosate (US EPA, 2006)**

### *3.1.5 General Subchronic and Chronic Systemic Toxicology*

One of the more consistent signs of subchronic or chronic exposure to glyphosate is loss of body weight. This effect has been noted in mice, rats, dogs, and rabbits. This observed weight loss is consistent with experimental data indicating that glyphosate may be an uncoupler of oxidative phosphorylation. Additionally, the loss of body weight observed was not associated with a significant decrease in food consumption. Other general and non-specific signs of toxicity include liver weight, blood chemistry (may suggests mild liver toxicity), liver pathology, and changes in pituitary weight (USDA, 2003). The results of several subchronic and chronic toxicity studies are presented in table L-5 and discussed in the subsequent paragraphs.

**Table L-5. Subchronic and Chronic Toxicity Profile of Glyphosate (US EPA, 2006)**

| <b>US EPA Guideline No./<br/>Study Type</b>                           | <b>Results</b>                                                                                                                                                                                |

One of the studies included in table L-5 is a 90-day oral toxicity study in rats exposed to AMPA. As noted in the table and previously discussed, AMPA is a metabolite of glyphosate, and in soil and environmental water samples it is found more regularly than glyphosate. AMPA is considered slightly more toxic than glyphosate. However, while AMPA is a common environmental metabolite, only trace amounts of it are formed in mammals, with the remainder being excreted unchanged. For this reason, direct exposures to AMPA, as an endogenous metabolite in animals, are encompassed by the existing toxicity data on glyphosate. For further discussion on the occurrence of environmental concentrations of glyphosate or its metabolite AMPA, see the technical report: *Potential Impacts to Wildlife, Amphibians, Plants, and Ecosystems from Increased Glyphosate and Other Chemical Usage* (appendix N).

Other studies conducted at the time of the 1993 reregistration of glyphosate include two subchronic feeding studies in rodents that showed effects in the blood and pancreas. In the first 90-day feeding study, Sprague-Dawley rats were fed glyphosate for three months in doses equivalent to 0, 63, 317, or 1,267 mg/kg/day for males and 0, 84, 404, or 1,623 mg/kg/day for females. Males and females in all treated groups showed increased serum phosphorus and potassium. The mid-dose group had increased serum glucose. Likewise, the high-dose had increased serum glucose, blood urea nitrogen, and serum alkaline phosphatase and an increased occurrence of pancreatic lesions. US EPA determined that based on these results, the no observed effect level (NOEL) is <63 mg/kg/day for males and <84 mg/kg/day for females. However, these results were considered only possibly treatment related and the NOEL dose for each sex was not determined definitively (US EPA, 1993).

In the second subchronic feeding study, CD-1 mice were fed diets containing 0, 250, 500 or 2,500 mg/kg/day of glyphosate for 90 days. The risk assessment parameters were set based on decreases of body weight gains in the high-dose males and females of about 24% and 18%, respectively. Based on the observed decrease in body weight gain, the NOEL for both sexes is 500 mg/kg/day and the LOEL is 2,500 mg/kg/day (US EPA, 1993).

### *3.1.6 Effects on Nervous System*

There was no evidence of neurotoxicity in any of the toxicology studies conducted and there are no data requirements for neurotoxicity studies. Moreover, analysis of detailed literature on health outcomes of accidental and intentional gross over-exposures, such as suicides, to glyphosate or its commercial formulations also do not implicate it in neurotoxicity effects. The weight of evidence suggests that any neurological symptoms associated with glyphosate exposures were secondary to other toxic effects and cannot be attributed to it directly (USDA, 2003). Also based upon a weight of evidence considerations the conduct of a developmental neurotoxicity study with glyphosate to evaluate the potential for developmental neurotoxic effects was not required (US EPA 2006; USDA, 2003; US EPA1993).

Some of the relevant studies are discussed in the following paragraphs. Many of the other neurological studies conducted presented results that were not considered scientifically robust and, therefore, are not discussed in further detail in this section (USDA, 2003).

Glyphosate has been tested for neurotoxicity in rats after both acute and subchronic exposures, and has been tested for delayed neurotoxicity in hens (USDA, 2003). In an acute study, 10 male and 10 female rats were given doses of 50, 100, or 200 mg of glyphosate a.e./kg and were observed for 2 weeks. In a subchronic study, 12 female and 12 male rats were exposed to glyphosate in their diet at concentrations of 2,000, 8,000, or 20,000 ppm for 13 weeks. In both studies, glyphosate was negative for signs of neurotoxicity. In a third study, twenty hens were given a single gavage dose of glyphosate at 2,000 mg/kg; a slight decrease in brain AchE activity occurred, but there were no signs of delayed motor ataxia or neuropathology (USDA, 2003).

An additional subchronic study in rats and mice, performed by the National Toxicology Program (NTP, 1992), suggests that glyphosate may produce histological changes in the salivary glands in both organisms. While glyphosate may produce changes of the salivary gland by acting through an adrenergic pathway or by producing an adrenergic-mediated stimulation through some indirect mechanism, the mechanism causing this effect is not clearly understood and no signs of neurotoxicity were noted (USDA, 2003).

In an investigation of the effects of glyphosate on sensory mechanisms, 1 mM or 10 mM dose of glyphosate was applied to the tongue of anesthetized gerbils. As a result, their taste tester response (to table salt, sugar, and acids) decreased. Due to the possibility of outside variables affecting experimentation, these results were not classified clearly as a glyphosate-induced neurological effect (USDA, 2003).

### 3.1.7 Effects on Immune System

Glyphosate has been tested for effects on the immune system in humans and experimental animals, in both *in vivo* and *in vitro* studies. In an *in vivo* study performed by Blakley (1997), mice were exposed to glyphosate in their drinking water, at concentrations of 0, 0.35, 0.70, or 1.05 percent, for 26 days; their antibody immune response was evaluated using sheep red blood cell challenge. The study found that the response in exposed mice did not differ from that of the unexposed mice (controls). Additionally, an *in vitro* study using human immunocompetent cells also indicated that glyphosate at concentrations ranging from 0.01 to 10  $\mu$ moles had no effect on the immune system (Flaherty et al., 1991). Furthermore, there is also no evidence to suggest that glyphosate causes dermal sensitization or morphologic abnormalities, in experimental animals, which could implicate an effect on the immune system (USDA, 2003).

In studies performed on humans, there has been no confirmation that glyphosate directly causes photoirritation, photosensitization, or allergic responses (Williams et al, 2000; Jauhiainen et al., 1991; Maibach, 1986). In a 1986 study by Maibach, a group of volunteers were exposed to Roundup via direct dermal application and no significant responses were observed.

### 3.1.8 Effects of Endocrine Function

Of the specific tests conducted to determine potential effects of glyphosate on the endocrine system, none have reported any potential estrogen, androgen, and/or thyroid mediated toxicity resulting from exposure to glyphosate (US EPA, 2006; USDA, 2003).

Glyphosate was inactive as an estrogen receptor agonist in MCF-7 human breast cancer cells (Lin and Garry, 2000) and in yeast and trout hepatocyte assays (Petit et al., 1997). Additionally, in another study, the steroidogenic acute regulatory (StAR) protein, which mediates the rate-limiting step in the mitochondrial synthesis of steroid hormones, was not disrupted by glyphosate; therefore, glyphosate did not inhibit steroid synthesis in MA-10 mouse Leydig tumor cells. In a third test, glyphosate, with surfactant, was found to inhibit steroid synthesis. For all of these studies, it should be noted that they were conducted *in vitro*, and were used to assess whether a plausible biological mechanism for glyphosate to act as an endocrine disruptor exists (USDA, 2003).

### 3.1.9 Reproductive and Teratogenic Effects

Exposure to glyphosate has been evaluated for its effects on reproduction and ability to cause birth defects (teratogenic effects). Most of the literature indicates that glyphosate does not directly cause reproductive or teratogenic effects (US EPA, 2006; 1993; USDA, 2003). Four studies on the maternal, reproductive, and development toxicity of glyphosate were submitted for reregistration of glyphosate in 1993 (US EPA, 2006; 1993). The studies are discussed in the following paragraphs and the results are presented in table L-6.

In the first study, Charles River COBS CD rats were dosed with 0, 300, 1,000, or 3,500 mg/kg/day of glyphosate by gavage during gestation days six through 19. The high dose dams showed signs of diarrhea; decreased mean body weight; breathing rattles; inactivity; red matter around the nose, mouth, forelimbs, and dorsal head; decreases in total implantations per dam and

fetuses per dam; and mortality. Developmental effects were also only seen in the high-dose group and included increased number litters and fetuses with unossified sternebrae and decreased mean fetal body weights. Based on these results, the maternal and developmental toxicity NOAEL and LOAEL are 1,000 mg/kg/day and 3,500 mg/kg/day, respectively (US EPA, 2006; 1993; USDA, 2003).

In a second developmental and maternal toxicity study, Dutch Belted rabbits administered 0, 75, 175, or 350 mg/kg/day during gestation days six through 27 showed treatment-related findings at the highest dose only. These effects included diarrhea, nasal discharge, and death. There were no developmental effects observed, which could be attributable to the high maternal mortality level (62.5% at the highest dose). The NOAEL and LOAEL for maternal toxicity are 175 mg/kg/day and 350 mg/kg/day, respectively (US EPA, 2006; 1993; USDA, 2003).

In a three-generation reproduction study on male and female Sprague-Dawley rats administered 0, 3, 10, or 30 mg/kg/day of glyphosate continuously through diet, increased incidence of focal tubular dilation of the kidney was seen in the high-dose male third generation pups. Therefore, the NOEL for reproductive toxicity is  $\geq 30$  mg/kg/day. The developmental toxicity NOAEL and LOAEL are 10 mg/kg/day and 30 mg/kg/day, respectively (US EPA, 2006; 1993; USDA, 2003).

A second two-generation reproduction study showed treatment-related effects at the high dose when Sprague-Dawley rats were administered 0, 100, 500, or 1,500 mg/kg/day of glyphosate continuously through the diet. These effects included soft stools in the F<sub>0</sub> and F<sub>1</sub> generations, decreased food consumption and body weight gain in the F<sub>0</sub> and F<sub>1</sub> generations during the growth period, and decreased body weight gain in the F<sub>1</sub> and F<sub>2</sub> generations during the second and third week of lactation. Based on these effects, the reproductive and developmental NOELs are 500 mg/kg/day and the reproductive and development LOELs are 1,500 mg/kg/day (US EPA 2006; 1993).

**Table L-6. Reproductive and Teratogenic Toxicity Profile for Glyphosate (US EPA, 2006)**

| Study Type                                                         | Results                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |

Additional studies conducted to evaluate the reproductive and teratogenic effects of glyphosate, include subchronic and chronic exposure studies, which attempted to examine the impacts of glyphosate exposure on morphology of reproductive organs, mammary glands, and endocrine glands (including the testis, ovary, pituitary, thyroid, adrenal, pancreas, parathyroid, and thymus). In both types no treatment-related effects on reproductive organs or endocrine glands were observed at or below the maximally tolerated dose of 20,000 ppm in the diet, in the chronic study (Stout and Ruecker, 1990) and 50,000 ppm in the subchronic study (NTP, 1992).

Furthermore, according to USDA (2003), two studies, by Yousef et al. (1996) and Schroeder and Hogan (1981), show conflicting results of glyphosate's effect on mating, fertility, and reproduction parameters (including libido level, ejaculate volume, sperm count, semen fructose level and osmolarity, and number of abnormal or dead sperm). Yousef et al. (1995) found that all of the effects seen in rabbits were statistically significant; however the study does not provide the actual doses used or specify the exact formulation. The study by Schroeder and Hogan (1981) suggests no treatment-related effects of glyphosate at doses of 3, 10, or 20 mg/kg body weight, although some changes in kidney morphology were observed at 30 mg/kg/day. The basis for inconsistency lies in the reporting and experimental design limitations and deficiencies in Yousef's study. Also, the use of gelatin capsules in Yousef et al. (1995) makes his study less comparable and relevant to potential human exposure (USDA, 2003).

In terms of effects in humans, several epidemiological studies have been conducted to assess the relationship between general, or overall, pesticide exposure, or assumed pesticide exposure, and reproductive health outcomes; however most have not characterized exposures to specific pesticides (Arbuckle and Sever, 1998). Of the few studies that have linked exposure to glyphosate to potential risks, no adverse reproductive effects were noted. For example, the Ontario Farm Health Study, three retrospective cohort studies (Arbuckle et al., 2001; Curtis et al., 1999; Savitz et al., 1997) collected data on the relationship between pregnancy outcomes and pesticide use among couples living on farms in Ontario. Risk of miscarriage, spontaneous abortions, and fecundity were all found to be unrelated to glyphosate formulation use and exposure (USDA, 2003).

### *3.1.10 Carcinogenicity and Mutagenicity*

The US EPA and the World Health Organization (WHO; 1994) have reviewed, in detail, information regarding the carcinogenicity and mutagenicity of glyphosate. In 1991, the US EPA classified glyphosate as a Group E carcinogen (evidence of non-carcinogenicity for humans). Likewise, based on three studies submitted (and discussed in the following paragraphs) for the reregistration of glyphosate in 1993, US EPA concluded that glyphosate is not carcinogenic at the levels tested (US EPA, 2006; 1993). The US EPA confirmed this decision again in their publication of tolerance for glyphosate in 2002 (US EPA, 2002).

In the first study considered during the reregistration of glyphosate in 1993, Sprague-Dawley rats were fed glyphosate at levels of 0, 3, 10, or 31 mg/kg/day in males and 0, 3, 11, or 34 mg/kg/day in females for 26 months. The high dose groups showed signs of increased incidence of thyroid C-cell carcinomas in females and interstitial cell testicular tumors, but the U.S. EPA determined that these neoplasms were not treatment-related, noted that the incidence of thyroid carcinomas was not statistically significant, and determined that the incidence of testicular tumors was within historical levels. Therefore, the US EPA determined that glyphosate was not considered carcinogenic in this study (US EPA, 1993).

A second carcinogenicity feeding study was also conducted using Sprague-Dawley rats fed diets containing 0, 89, 362, or 940 mg/kg/day in males and 0, 113, 456, or 1183 mg/kg/day in females of glyphosate. The low- and high-dose males and females showed an increase incidence of pancreatic islet cell adenomas and hepatocellular (liver) adenomas. The mid- and high-dose animals also showed an increased incidence of thyroid C-cell adenomas. However, the pancreatic islet cell adenomas were not associated with a statistically significant positive dose-related trend, a progression to carcinomas, or dose-related increase in pancreatic hyperplasia. Additionally, statistically significant increase in incidence of hepatocellular adenomas was not seen and the incidence was within historical range, there was no progression to carcinomas, and the incidence of hyperplasia was not compound-related. In terms of thyroid C-cell adenomas, there was no statistically significant dose-related trend in occurrence or a statistically significant increase in incidence, no progression to carcinomas, and no significant dose-related increase in hyperplasia. Therefore, glyphosate was not considered to be carcinogenic (US EPA, 1993)

Another carcinogenicity study involved an 18-month feeding study conducted with CD-1 mice using doses of glyphosate equivalent to 0, 150, 750, or 4500 mg/kg/day. The effects in the high-dose group included decreased body weight gain in both sexes, increased hepatocellular hypertrophy, hepatocellular necrosis and interstitial nephritis in males, increase incidence of proximal tubule epithelial basophilia and hypertrophy in females, and an increase incidence of renal tubular adenomas in males. Based the effects listed above, the NOAEL is 750 mg/kg/day for both sexes and the LOAEL is 4500 mg/kg/day for both sexes. However, it was determined by the US EPA and confirmed by other experts that the adenomas occurred spontaneously and that glyphosate is not considered carcinogenic based on the results of this study (US EPA, 2006; 1993).

In the US EPA (2002) assessment, US EPA addressed concerns about studies performed by Hardell and Erickson (1999a,b) which found that individuals in Sweden with a history of glyphosate exposure had an increased risk of developing non-Hodgkin lymphoma. A second study by Hardell and Erickson (199b) found this risk to be statistically significant. In response, the US EPA concluded that these studies did not establish a definitive link to cancer and their results were based on unverified recollection of exposure; as a result, the US EPA maintained its classification of glyphosate as a Group E carcinogen.

In terms of its mutagenicity, glyphosate has been shown to cause an increase in chromosomal aberration in a plant (*Allium sp.*) associated with cell abnormalities in spindle fiber (Rank et al. 1993), DNA adduct formation in mice (Reluso et al., 1998), and single strand DNA breaks in mice (Bolognesi et al., 1997). Reports on *in vitro* studies conducted by Vyse and Vigfusson (1979) and Vigfusson and Vyse (1980) indicate a significant increase in sister chromatid exchanges in human lymphocytes and conclude that glyphosate is a slight mutagen. Another positive assay was confirmed in a fruit fly study (Kaya et al., 2000; Kale et al., 1995) as well as in a study of lymphocyte cultures (Lioi et al., 1998a; Lioli et al., 1998b). Most of the remaining screening studies for mutagenicity, however, were negative.

For example, four mutagenicity studies were submitted for the reregistration of glyphosate in 1993. These studies included a gene mutation assay in an Ames Test on *Salmonella typhimurium* strains, a gene mutation assay in Chinese hamster ovary cells/hypoxanthine – guanine – phosphoribosyl transferase assay, a Structural Chromosomal Aberration Assay in male and female Sprague-Dawley rats, and a combined study employing a rec-assay using *B. subtilis* a reverse mutation assay using *E. coli* and *Salmonella typhimurium* strains. None of these studies showed a mutagenic or clastogenic response. As a result, the US EPA concluded that glyphosate is not a mutagen (USDA, 2003; US EPA, 2002; 1993).

#### 3.1.11 Irritation and Sensitization

According to EPA, glyphosate is classified as mildly irritating to the eyes (Category III) and slightly irritating to the skin (Category IV) based on data collected from skin and eye irritation studies during the registration process (US EPA 2006; 1993). Different formulations of glyphosate have different irritation patterns (e.g., the free acid of glyphosate is severely irritating to the eyes, but the IPA salt of the glyphosate is nonirritating to the skin and eyes) (USDA, 2003). Additionally, skin sensitization tests for glyphosate were all negative (US EPA, 2006; 1993).

### *3.1.12 Systemic Toxic Effects from Dermal Exposure*

System toxic effects from chronic dermal exposure are less damaging than those from chronic oral exposure, since glyphosate is poorly absorbed from the skin. Acute dermal exposure effects are similar to those of acute oral exposure effects (USDA, 2003). The US EPA classified glyphosate as a Category III for oral and dermal toxicity. The LD<sub>50</sub> value for the acute oral toxicity of glyphosate is >5,000 mg/kg (US EPA, 2006).

The US EPA RED for glyphosate (US EPA, 1993) gives more insight on the dermal toxicity of glyphosate. It cites a 1982 study (MRID 00098460) with rabbits in which glyphosate was applied to intact and abraded skin at doses of 10, 1,000, or 5,000 mg/kg/day, five days a week, for three weeks. The effects were minimal and included, slight irritation of the abraded skin, decreased food consumption, and decreased serum lactic dehydrogenase activity at 5,000 mg/kg. In a more recent study by Pinto (1996), dermal doses of 250, 500, or 1,000 mg/kg/day caused no effects on body weight, food consumption, hematology, clinical chemistry, or organ weights. There were also no signs of irritation or pathologic changes in tissue.

### *3.1.13 Inhalation Effects*

The US EPA did not require an acute inhalation study for technical grade glyphosate (US EPA, 2006; 1993) because of its low volatility rate. The acute inhalation LC<sub>50</sub> value of the isopropylamine salt glyphosate is >6.37 mg/L, which is equivalent to a finding of no mortality in any of the five rats of each sex exposed to this concentration for four hours (USDA, 2003). A study conducted by Jamison et al., (1986) exposed a group of human volunteers to glyphosate treated flax dust and untreated flax dust. The glyphosate treated dust consistently caused a decrease in respiratory function; however, this may have been due to a greater distribution of smaller dust particles, which are more easily inhaled, in the glyphosate treated dust.

### *3.1.14 Toxic Relevance of Surfactants in Glyphosate Formulations*

Various formulations of glyphosate contain POEA at a level of up to approximately 20 percent (200 g/L). Tallow contains a variety of fatty acids (e.g., oleic, palmitic, stearic, myristic, and linoleic acids), as well as smaller amounts of cholesterol, arachidonic, elaidic, and vaccenic acids. While surfactants are typically classified as “inert” components in herbicides, they are not toxicologically inert and in many cases they are found to be more toxic than the herbicide itself (USDA, 2003).

A study evaluating the toxicity of the POEA surfactant includes a series of teratology tests in rats using glyphosate (98.7% purity), POEA used in glyphosate formulations, and the phosphate ester neutralized POEA. Groups of pregnant female rats were dosed with glyphosate at 300, 1,000, or 3,500 mg/kg/day; POEA at 15, 100, or 300 mg/kg/day, or the neutralized POEA at 15, 50, or 150 mg/kg/day on days 6 through 19 of gestation. Results indicated that severe maternal poisoning occurred at the 3,500 mg/mg/day dose of glyphosate, in association with reduced fetal body weight and sternal ossification, as well as fetal death. At a dose of 300 mg/kg/day of POEA and

150 mg/kg/day of neutralized POEA maternal deaths were also reported. Another noteworthy result in dams included the fact that signs of mild clinical toxicity and decrease food consumption occurred at a dose of 100 mg/kg/day POEA surfactant. No fetotoxic effects were reported at any dose level. Based on these results, the NOAELs for glyphosate, POEA, and neutralized POEA were 1000 mg/kg/day, 15 mg/kg/day, and 50 mg/kg/day, respectively (USDA, 2003).

There has been some debate as to the acute toxicity of POEA and the determination of its LD<sub>50</sub> value, as compared to glyphosate; however, it is generally agreed that the acute toxicity of glyphosate formulations in humans (glyphosate and surfactant, LD<sub>50</sub> in rats 5400 mg/kg/day) is almost equivalent to that of glyphosate (LD<sub>50</sub> in rats 5600 mg/kg/day) (USDA, 2003). Additionally, based on drinking water studies on both glyphosate and Roundup (glyphosate with POEA), the surfactant does not affect the rapid elimination rate of glyphosate in mammals (NTP, 1992).

### *3.1.15 Toxic Relevance of Impurities in Glyphosate Formulations*

#### *3.1.15.1 N-nitrosoglyphosate (NNG)*

Technical grade glyphosate contains at least one impurity, N-nitrosoglyphosate (NNG). The US EPA determined that the NNG content in glyphosate was not toxicologically significant because more than 92% of the individual technical glyphosate samples tested contained less than 1.0 ppm NNG. There is general concern for the carcinogenic potential of nitroso compounds; however, it is hard to quantify (USDA, 2003; US EPA 1993).

#### *3.1.15.2 4-Dioxane*

1,4-Dioxane is an impurity in POEA, and the US EPA considers it to be a carcinogen (Class B2: Probable human carcinogen) and has derived a cancer potency factor (slope factor) of 0.011 mg/kg/day. 1,4-Dioxane is present in Roundup at a level of approximately 0.03% (Monsanto, 1999) or 300 mg/l (330 ppm). It has been demonstrated that dioxane does not present unique toxic effects; therefore, its toxicity (except its role as a carcinogen) is encompassed by the available toxicity data on glyphosate (USDA, 2003).

## **3.2 Exposure Assessment**

### *3.2.1 Overview*

As previously stated, there are five herbicide EUPs (end-use products) containing glyphosate that are recommended for use on a specific brand of GT alfalfa called Roundup Ready alfalfa. These products include: Roundup Original Max®, Roundup Weather Max®, and Roundup Ultra Max II®, Honcho® and Honcho Plus® (Greenbook, 2008; Monsanto, 2008). Each of these products contains between 41 and 49% glyphosate (Monsanto, 2007a; 2007b; 2007c; 2007d; 2004). Independent consideration of other ingredients in the EUPs is beyond the scope of this exposure assessment. For purposes of this analysis, exposure estimates to the chemical glyphosate are presented as opposed to exposure estimates to the EUPs. This is because toxicological data on

the EUPs, which are required to assess risk to workers, were not available at the time of the analysis.

### *3.2.2 Routes of Exposure*

The general public is not at a high risk of exposure to substantial levels of glyphosate under typical conditions (US EPA, 1993; USDA, 2003). Dermal and inhalation routes of exposure are not considered in this analysis because it is assumed that GT alfalfa will not be grown by members of the general public. Thus, it is assumed that the general public will not directly come in contact with or inhale herbicides recommended for use on GT alfalfa. It is, however, assumed that members of the general public may be exposed orally to these herbicides via consumption of foods that have been treated by herbicides containing glyphosate.

In the 1993 US EPA RED for glyphosate, the US EPA conducted a dietary risk assessment and determined that non-nursing infants under one year of age are at highest risk of adverse effects associated with glyphosate exposure (US EPA, 1993). The US EPA completed an additional risk assessment for glyphosate in 2006 to address its specific use on Indian mulberry and dried peas (US EPA). In this later assessment, the US EPA also found that infants under one year of age are at greatest risk. The results of these risk assessments are discussed in further detail in section 3.4.

Because oral exposure scenarios are feasible, this exposure analysis estimates potential glyphosate exposure associated with consumption of fruit and vegetables that have been treated with an herbicide containing glyphosate. It is not anticipated that alfalfa will be consumed in large quantities directly by humans; alfalfa sprouts are consumed generally in relatively small quantities. Because small quantities of alfalfa sprouts are consumed, potential glyphosate consumption was estimated by modeling contamination of other crops growing nearby alfalfa fields.

Consumption of crops treated with a glyphosate-based herbicide is rare because treated crops show signs of damage, making the contamination easily identifiable to the consumer. However, it cannot be assumed that consumption will never occur, thus, exposure scenarios evaluated in this analysis include adults' chronic and acute consumption of contaminated fruit and vegetation. Exposures of two additional sensitive subpopulations including the elderly and infants under one year of age are also estimated. Additional oral exposure scenarios might include consumption of contaminated water or fish, but analysis of these exposure pathways was not conducted for this assessment. Fish do not bioaccumulate glyphosate; in 2003, the USDA evaluated several water exposure scenarios, including consumption of contaminated surface water, and none were considered a risk to human health.

### *3.2.3 Application Rates*

Maximum single application rates of products containing glyphosate for GT crops range from 0.56 pounds of glyphosate a.e. per acre up to 3.75 pounds of glyphosate a.e. per acre (Monsanto, date unknown). Application rates were determined using specific product labels for each EUP

recommended for use on GT alfalfa (Monsanto, 2007a; 2007f; 2007c; 2007d; 2005b; 2005c; 2004). The maximum label single use rate for GT alfalfa is 1.55 pounds glyphosate a.e. per acre. Application rates on these products were presented in volume (i.e., quarts or ounces) of active ingredient per acre. These values were converted to mass (i.e., pounds) per acre by multiplying the application volume by the density of the EUP (See equations L-1 and L-2).

Equation L-1

$$\text{Density} = \text{Mass} / \text{Volume}$$

thus,

Equation L-2

$$\text{Mass} = \text{Density} * \text{Volume}$$

Density values were provided by material safety data sheets (MSDS) for each EUP. When product density was not available, the specific gravity of the EUP was used to calculate density. The specific gravity is the ratio of the product density to the density of water. It was assumed that the density of water is 1000 kg/m<sup>3</sup> (See equations L-3 and L-4).

Equation L-3

$$\text{Specific gravity} = \text{Product density} / \text{Water density}$$

thus,

Equation L-4

$$\text{Product density} = \text{Specific gravity} * \text{Water density}$$

Labels also provided application rates for the EUP as opposed to the chemical alone. Because this exposure analysis focuses on the chemical as opposed to the EUP, the percent a.e. (i.e., glyphosate) reported by the product label was considered in the exposure equation (See equation L-5). The percent of glyphosate in EUPs ranged from 41 and 49% (see table L-1).

Equation L-5

$$\text{Application rate of glyphosate} = \text{Application rate of EUP} * \text{Percent glyphosate in EUP}$$

Maximum application rates of the five EUP recommended for use on GT alfalfa are presented in table L-7. Please refer to appendix L-4 of this technical report for further explanation of application rate calculations.

**Table L-7. Maximum Application Rates of EUPs for Use on Glyphosate-Tolerant Alfalfa**

| Product               | Single Use Application Rate | Reference                     |
|-----------------------|-----------------------------|-------------------------------|
| Honcho®               | 2.0 lb a.e./acre            | Monsanto, 2007a; 2007e        |
| Honcho Plus®          | 2.0 lb a.e./acre            | Monsanto, 2007b; 2007f        |
| Roundup Original MAX® | 1.9 lb a.e./acre            | Monsanto, 2007c               |
| Roundup WeatherMAX®   | 1.9 lb a.e./acre            | Monsanto, 2007d; 2005a; 2005b |
| Roundup Ultra MAX II® | 1.9 lb a.e./acre            | Monsanto 2005c; 2004; 2003    |

### 3.2.4 General Public Exposure Scenarios

#### 3.2.4.1 Acute Consumption Scenario

Exposure scenarios for acute consumption were provided by USDA (2003) and acute exposure algorithms were provided by SERA (2006) in a supplemental calculations worksheet presented to USDA. In this scenario, an individual is exposed through consumption of contaminated vegetation or fruit after a single acute spray application of glyphosate. An acute oral dose ( $OD_{acute}$ ) of glyphosate may be estimated by multiplying the concentration of the chemical present on the contaminated vegetation or fruit ( $Conc$ ) by the amount of that vegetation or fruit consumed per day per unit body weight of the exposed individual ( $Amnt$ ) (See Equation L-6). The estimate of the concentration of the chemical present on the contaminated vegetation or fruit ( $Conc$ ) is calculated by multiplying the application rate ( $AR$ ), the residue rate ( $RR$ ), the drift proportion ( $Drift$ ), and the proportion of chemical remaining after washing ( $Prop$ ) (See equation L-7).

#### Equation L-6

$$OD_{acute} = Conc * Amnt$$

Where:

|              |   |                                                                      |
|--------------|---|----------------------------------------------------------------------|
| $OD_{acute}$ | = | estimated acute oral dose (mg/kg bw)                                 |
| $Conc$       | = | concentration on vegetation (mg/kg food item)                        |
| $Amnt$       | = | amount consumed per day per unit body weight (kg food/kg BW per day) |

#### Equation L-7

$$Conc = AR * RR * Drift * Prop$$

Where:

|         |   |                                               |
|---------|---|-----------------------------------------------|
| $Conc$  | = | concentration on vegetation (mg/kg food item) |
| $AR$    | = | application rate (lbs/acre)                   |
| $RR$    | = | residue rates (mg/kg food per lb/acre)        |
| $Drift$ | = | drift proportion (unitless)                   |
| $Prop$  | = | proportion remaining after washing (unitless) |

The amounts of fruit or vegetables consumed by individuals (*Amnt*) are based on the estimates from the US EPA's *Exposure Factor's Handbook* (US EPA, 1997). Data are based on US EPA's analysis of the USDA's (1991) nationwide survey called the Consumption of Food Intake by Individuals (CSFII) from 1989 to 1991. Data are in kilograms of fruit or vegetables consumed per kilogram of body weight of the individual per day (US EPA, 1997). Data are already normalized to the body weights of the exposed individuals. Amounts of fruits and vegetables consumed by adults aged 20 to 39 years, elderly individuals aged 70 years and older, and infants under one year were collected. For each age category, the mean consumption rate is presented as the central estimate of consumption. Also for each age category, the 25<sup>th</sup> percentile of the distribution of consumption rates for the entire population of the age category evaluated in the CSFII is presented as the lower estimate, and the 100<sup>th</sup> percentile of the distribution is presented as the upper estimate of consumption. Consumption rates for fruits and vegetables by age category are presented in table L-8 and table L-9 respectively.

**Table L-8. Amount of Fruit Consumed by Age Category (in kg of fruit per kg of body weight per day) (USEPA, 1997)**

| Age Group         | Mean<br>(Central Estimate) | 25 <sup>th</sup> Percentile<br>(Lower Estimate) | 100 <sup>th</sup> Percentile<br>(Upper Estimate) |
|-------------------|----------------------------|-------------------------------------------------|--------------------------------------------------|
| Adult (20-39 yrs) | 1.88E-03                   | 0                                               | 4.16E-02                                         |
| Elderly (70+ yrs) | 2.98E-03                   | 8.90E-04                                        | 1.50E-02                                         |
| Infants (<1 yr)   | 1.49E-02                   | 0                                               | 2.11E-01                                         |

**Table L-9. Amount of Vegetables Consumed by Age Category (in kg of fruit per kg of body weight per day) (USEPA, 1997)**

| Age Group         | Mean<br>(Central Estimate) | 25 <sup>th</sup> Percentile<br>(Lower Estimate) | 100 <sup>th</sup> Percentile<br>(Upper Estimate) |
|-------------------|----------------------------|-------------------------------------------------|--------------------------------------------------|
| Adult (20-39 yrs) | 3.53E-03                   | 2.06E-03                                        | 1.71E-02                                         |
| Elderly (70+ yrs) | 4.07E-03                   | 2.47E-03                                        | 1.89E-02                                         |
| Infants (<1 yr)   | 6.80E-03                   | 0                                               | 4.50E-02                                         |

An application rate (*AR*) of 2.0 pounds a.e. per acre was used because it is the more conservative of the single use application rates for the five EUPs recommended for use on GT alfalfa (See table L-7). This rate is consistent with the labeled maximum single use rate of 1.55 a.e. pounds glyphosate per acre for application on GT alfalfa.

Residue rates (*RR*) were based on an empirical relationship between application rate and concentration on food developed by Fletcher et al. (1994). Fletcher et al. used the Kenaga nomogram, a device developed by EPA to predict maximum potential pesticide residue levels. Fletcher et al. conducted a review to determine if the residue levels predicted by the nomogram are comparable to values reported in the literature. The authors concluded that the Kenaga nomogram predicts values for residue rates that are comparable to values reported in the literature. According to Fletcher et al., the estimated values range from 7 mg/kg food per lb/acre to 15 mg/kg food per lb/acre for fruit and from 45 mg/kg food per lb/acre to 135 mg/kg food per lb/acre for vegetation.

It was assumed that both the drift proportion (*Drift*) and the proportion of chemical remaining on the fruit or vegetation after washing (*Prop*) are equal to one. The drift proportion or spray drift of a pesticide is defined by US EPA as the physical movement of a pesticide or herbicide

through the air at the time of application to a site that is not intended for application (US EPA, 2008). A drift proportion of one assumes that the same amount of pesticide is applied to target and non-target crops. In this case, the herbicide target is GT alfalfa. It is unlikely that non-target fruit or vegetation would have the same level of contamination as the target plant since they are likely to grow in different fields. Thus, a drift proportion of one is a highly conservative estimate. The proportion of the chemical remaining on the fruit or vegetation is likely to be reduced after washing, thus one is also a highly conservative estimate.

Central, lower, and upper bound exposure estimates from ingestion of fruit and vegetables were calculated for the acute oral consumption exposure scenarios for adults, the elderly, and infants. Results are presented in tables L-10 and L-11. Please refer to the calculations worksheet submitted with this report for further explanation of exposure estimate calculations.

**Table L-10. Exposure Estimates for Acute Consumption of Fruit by Age Category (in mg/kg body weight per day)**

| Age Category      | Central Estimate | Lower Estimate | Upper Estimate | Worksheet |
|-------------------|------------------|----------------|----------------|-----------|
| Adult (20-39 yrs) | 2.63E-02         | 0              | 1.25E+00       | 1         |
| Elderly (70+ yrs) | 4.17E-02         | 1.25E-02       | 4.50E-01       | 2         |
| Infants (<1 yr)   | 2.09E-01         | 0              | 6.32E+00       | 3         |

**Table L-11. Exposure Estimates for Acute Consumption of Vegetables by Age Category (in mg/kg body weight per day)**

| Age Category      | Central Estimate | Lower Estimate | Upper Estimate | Worksheet |
|-------------------|------------------|----------------|----------------|-----------|
| Adult (20-39 yrs) | 3.18E-01         | 1.85E-01       | 4.61E+00       | 4         |
| Elderly (70+ yrs) | 3.66E-01         | 2.22E-01       | 5.11E+00       | 5         |
| Infants (<1 yr)   | 6.12E-01         | 0              | 1.21E+01       | 6         |

#### 3.2.4.2 Chronic Consumption Scenario

Exposure scenarios for chronic consumption scenario were provided by USDA (2003) and chronic exposure algorithms were provided by SERA (2006) in a supplemental calculations worksheet presented to USDA. In this scenario, the contaminated fruit or vegetation is exposed to glyphosate for a defined period of exposure ( $ED$ ). The general public's consumed dose of glyphosate ( $OD_{chronic}$ ) may be estimated by multiplying the time-weighted average concentration of consumed vegetation ( $C_{TWA\ CON}$ ) by the amount of vegetation or fruit consumed per day per unit body weight (See equation L-8). The  $C_{TWA\ CON}$  is calculated by multiplying the time-weighted average concentration on food over the exposure duration ( $Con_{TWA}$ ) by the proportion of the chemical remaining after the food item is washed ( $Prop$ ) (See equation L-9). The time-weighted average concentration on food over the exposure duration ( $Con_{TWA}$ ) is estimated in equation L-10 (De Sapia, 1976). The concentration at a specific time ( $Conc_{ED}$ ) can be calculated based on the initial concentration on food ( $C_0$ ), assuming a first-order decrease in concentrations in contaminated food (See equation L-11).  $C_0$  is estimated by multiplying the application rate by the residue rate ( $RR$ ) and the proportion of anticipated spray drift (See equation L-12). The decay coefficient ( $k$ ) is estimated by dividing the natural log of 2 ( $Ln(2)$ ) by the half-life of the chemical on the food item ( $t_{50}$ ) (See equation L-13).

### Equation L-8

$$OD_{chronic} = C_{TWA\ CON} * Amnt$$

Where:

|                |   |                                                                                          |
|----------------|---|------------------------------------------------------------------------------------------|
| $OD_{chronic}$ | = | estimated chronic oral dose (mg/kg bw)                                                   |
| $C_{TWA\ CON}$ | = | time-weighted average concentration on consumed food item over exposure duration (mg/kg) |
| $Amnt$         | = | amount consumed per day per kilogram of body weight (kg food item/kg BW per day)         |

### Equation L-9

$$C_{TWA\ CON} = Con_{TWA} * Prop$$

Where:

|                |   |                                                                                               |
|----------------|---|-----------------------------------------------------------------------------------------------|
| $C_{TWA\ CON}$ | = | time-weighted average concentration on consumed food item over exposure duration (mg/kg food) |
| $Con_{TWA}$    | = | time-weighted average concentration on food over exposure duration (mg/kg food)               |
| $Prop$         | = | proportion remaining after food item is washed (unitless)                                     |

### Equation L-10

$$Con_{TWA} = C_0 \times (1 - e^{-k \cdot ED}) \div (k * ED)$$

Where:

|             |   |                                                                                 |
|-------------|---|---------------------------------------------------------------------------------|
| $Con_{TWA}$ | = | time-weighted average concentration on food over exposure duration (mg/kg food) |
| $C_0$       | = | initial concentration on vegetation (mg/kg food)                                |
| $k$         | = | decay coefficient (per day)                                                     |
| $ED$        | = | time (days)                                                                     |

### Equation L-11

$$Conc_{ED} = C_0 * e^{-k \cdot ED}$$

Where:

|             |   |                                                       |
|-------------|---|-------------------------------------------------------|
| $Conc_{ED}$ | = | concentration on food at a specific time (mg/kg food) |
| $C_0$       | = | initial concentration on vegetation (mg/kg food)      |
| $k$         | = | decay coefficient (per day)                           |
| $ED$        | = | time (days)                                           |

### Equation L-12

$$C_0 = AR * Drift * RR$$

Where:

|       |   |                                                 |
|-------|---|-------------------------------------------------|
| $C_0$ | = | initial concentration on food item (mg/kg food) |
| AR    | = | application rate (lbs/acre)                     |
| Drift | = | spray drift (unitless)                          |
| RR    | = | residue rate (mg/kg food per lb/acre)           |

### Equation L-13

$$k = \ln(2) / t_{50}$$

Where:

|          |   |                             |
|----------|---|-----------------------------|
| k        | = | decay coefficient (per day) |
| $\ln(2)$ | = | natural log of 2 (unitless) |
| $t_{50}$ | = | half-life of food (days)    |

For the chronic oral exposure scenarios, a number of variables are comparable to variables incorporated in the equations used to estimate acute exposure. Values for the amount of fruit and vegetables consumed (*Amnt*) are the same as the values used for the acute oral exposure scenarios. Consumption rates for each age category (adults aged 20-39 years, elderly individuals aged 70+ years, and infants under 1 year) were taken from EPA's *Exposure Factors Handbook* (USEPA, 1997). The proportion of the chemical remaining after a food item is washed (*Prop*) is also assumed to be one. The same application rate (AR) of 2 pounds of glyphosate a.i per acre was also used and the same residue rates (RR) for fruits and vegetables from Fletcher et al. (1994) were assumed for the chronic exposure scenario and the acute exposure scenario. The same spray drift (*Drift*) assumption of one was also assumed for the chronic scenario.

Several additional default values were required for the chronic exposure scenarios that were not required for the acute exposure scenario. An exposure duration (*ED*) of 90 days was assumed based on USDA's assumption that a harvesting season will last approximately three months (USDA, 2003). Thus, it is assumed that an individual could be exposed for 90 consecutive days during this season. Calculation of the decay coefficient (*k*) required a half life of the chemical on food. Siltanen et al. (1981) used the dissipation on the vegetation to estimate the half-life of glyphosate on fruits and vegetation. The study reported a half-life of 46 days which is the value assumed in this analysis.

Central, lower, and upper bound chronic exposure estimates from ingestion of fruits and vegetables were calculated for adults, the elderly, and infants. Results are presented in tables L-12 and L-13. Please refer to the calculations worksheet submitted with this report for further explanation of exposure estimate calculations.

**Table L-12. Exposure Estimates for Chronic Consumption of Fruit by Age Category(in mg/kg body weight per day)**

| <b>Age Category</b> | <b>Central Estimate</b> | <b>Lower Estimate</b> | <b>Upper Estimate</b> | <b>Worksheet</b> |
|---------------------|-------------------------|-----------------------|-----------------------|------------------|
| Adult (20-39 yrs)   | 1.44E-02                | 0                     | 6.83E-01              | 7                |
| Elderly (70+ yrs)   | 2.29E-02                | 6.82E-03              | 2.46E-01              | 8                |
| Infants (<1 yr)     | 1.14E-01                | 0                     | 3.46E+00              | 9                |

**Table L-13. Exposure Estimates for Chronic Consumption of Vegetables by Age Category (in mg/kg body weight per day)**

| <b>Age Category</b> | <b>Central Estimate</b> | <b>Lower Estimate</b> | <b>Upper Estimate</b> | <b>Worksheet</b> |
|---------------------|-------------------------|-----------------------|-----------------------|------------------|
| Adult (20-39 yrs)   | 1.74E-01                | 1.01E-01              | 2.52E+00              | 10               |
| Elderly (70+ yrs)   | 2.00E-01                | 1.22E-01              | 2.80E+00              | 11               |
| Infants (<1 yr)     | 3.35E-01                | 0                     | 6.65E+00              | 12               |

### 3.3 Dose-presonse assessment

#### 3.3.1 Overview

An RfD is defined as a level of exposure that will not result in any adverse effects in any individual. The RfD value for glyphosate proposed by the U.S. EPA Office of Pesticide Programs is 2 mg/kg/day, and is based on a teratogenicity study in rabbits in which there were no observed effects in offspring at any dose level, and maternal toxicity was noted at 350 mg/kg/day with a NOAEL of 175 mg/kg/day (Rodwell et al., 1980b). The RfD of 2 mg/kg/day was derived by dividing the NOAEL by an uncertainty factor of 100 – 10 for sensitive individuals and 10 for species-to-species extrapolation – and rounding the result to one significant figure (US EPA, 2006; 2002; 1993).

#### 3.3.2 Existing Guidelines

The current section of this risk assessment attempts to take into account the two, US EPA Office of Pesticide Programs (US EPA OPP) proposed, chronic reference doses (RfDs) for glyphosate and the WHO's comparable proposed ADI (acceptable daily intake) in its analysis. As discussed in the previous paragraph, the RfD of 2 mg/kg/day was derived from a teratogenicity study in rabbits and was first derived in the 1993 RED document for glyphosate (US EPA, 1993). The US EPA has also derived an RfD for glyphosate of 0.1 mg/kg/day (US EPA, 1990). This RfD was originally derived by the US EPA's Integrated Information System (IRIS) workgroup and is still posted on IRIS. This value is based on a dietary 3-generation reproduction study by Schroeder and Hogan (1981), in which rats were exposed to glyphosate in their diet and no adverse effects were observed. The NOAEL was 10 mg/kg/day and an uncertainty factor of 100 was used.

The ADI proposed by WHO (1994) is based on a life-time feeding study in rats, as opposed to a reproductive toxicity study. A study by Lankas and Hogan (1981) supplied male and female rats a daily dose (0, 3.1, 10.3, or 31.5 mg/kg/day in males; 0, 3.4, 11.3, or 34.0 mg/kg/day in females) of glyphosate in their diet for 26 months. No effects were observed in any of the animals at any of the dose levels; therefore, WHO used a NOAEL of 31.5 mg/kg/day and an uncertainty factor of 100 to derive the ADI.

US EPA's Office of Drinking Water (US EPA ODW) proposed a 10-day health advisory for glyphosate of 17.5 mg/L, based on the NOAEL of 175 mg/kg/day, and a longer-term health advisory of 1 mg/L, based on the U.S. EPA RfD of 0.1 mg/kg/day. The US EPA ODW also derived a short-term RfD of 2 mg/kg/day, which is identical to the chronic RfD proposed by US EPA OPP.

### 3.3.3 *Dose-Response and Dose-Severity Relationships*

A threshold and non-threshold multistage model was used to estimate the LD<sub>50</sub> in humans. Both models approximated the LD<sub>50</sub> to be 3,000 mg/kg/day, similar to the range of 2000 to 6000 mg/kg reported in experimental mammals. Additionally, the threshold version of the multistage model was also used to yield an estimate of the threshold dose of 445 mg/kg for systemic toxic effects. Below this dose, it is assumed that no individual in the population will respond (USDA, 2003).

In addition, dose severity relationships were analyzed for experimental mammals and humans. The available animal data were characterized using four standard severity levels: NOEL (no observed effect level), NOAEL (no observed adverse effect level), AEL (adverse effect level), and FEL (frank effect level). Furthermore, three different groups of end points were determined: general systemic toxic effects, reproductive or developmental effects, and acute LD<sub>50</sub> values. Although the exposure periods for these studies ranged from one day to greater than two years, glyphosate is rapidly excreted from the body; therefore, duration of exposure is not an important parameter in assessing the toxicity of glyphosate (USDA, 2003).

The data for experimental animals was further analyzed using categorical regression analysis in the next step of assessing the dose-severity relationships, which correlates categorical responses with factors that may influence the response. Results of the categorical regression indicate that the probabilities of an adverse effect at the RfD of 0.1 mg/kg/day is 0.0005, at 1 mg/kg/day is 0.003, and at a dose of 10 mg/kg/day is 0.12. From these results, it was inferred that an RfD of 2 mg/kg is protective. It was further determined that the probability of a frank toxic effect (a sufficiently severe effect that can be observed in the whole organism without the use of invasive methods) at the RfD of 0.1 mg/kg/day is 0.00005 and at the RfD of 2 mg/kg/day increases to 0.0006 (USDA, 2003).

The consistency between the categorical analysis in experimental animals and the dose-response analysis using the multistage model for humans is relatively good. At 445 mg/kg, the estimated threshold of human lethality, the probability of observing a frank toxic effects is approximately 0.04. At this dose in the non-threshold version of the multi-stage model, the probability is 0.02. At the estimated human LD<sub>50</sub> of approximately 3000 mg/kg, the probability of observing an adverse or frank effect, as determined by a categorical regression using two categories, is 0.7.

For glyphosate, the data suggests that humans are no more sensitive than experimental animals. Subsequently, this suggests that the current and proposed RfDs may be overly protective by a factor of 10 or greater.

### 3.3.4 *Susceptible Populations*

On the basis of developmental studies in rats and rabbits and reproductive findings in rats, glyphosate exhibited no evidence of increased qualitative and quantitative susceptibility. Additionally, an acute RfD was not established for any population subgroup or the general population, including infants and children, based on the absence of an appropriate toxicological endpoint attributable to a single exposure (dose), including maternal toxicity in developmental toxicity studies (US EPA, 2006).

### 3.3.5 *RfD Values Used in Risk Assessment of Glyphosate*

The database on glyphosate is large, complex, and open to many potential interpretations. For example, according to a 1986 determination by the Joint Food and Agricultural Organization of the United Nation (FAO)/World Health Organization (WHO) on Pesticides Residues (JMPR), an Allowable Daily Intake (ADI) of glyphosate is 0.3 mg/kg *per se*. This was based on a 26-month feeding study in rats with a resulting NOEL of >31 mg/kg/day and an uncertainty factor of 100. However, the US EPA determined a NOAEL of 175 mg/kg/day and an uncertainty factor of 100, because maternal mortality was observed at the highest dose group. As a result, in 1992, the US EPA's Office of Pesticide Program Reference Dose Peer Review Committee recommended that the reference dose for glyphosate be set at 2 mg/kg/day (USDA, 2006) for longer-term exposures. The US EPA's Office of Drinking Water also recommended a value of 2 mg/kg/day for short-term exposures. As a result, the same RfD is used for both short- and long-term exposures; however, due to a lack of significant dose-response data for glyphosate, this approach was deemed appropriate (USDA, 2006; US EPA 2002; 1993). Glyphosate endpoints for this risk assessment are summarized in table L-14 below.

**Table L-14. Summary of Toxicological Doses and Endpoints for Chemical for Use in Human Health Risk Assessments (US EPA, 2006)**

| <b>Exposure Scenario</b>                                                                                              | <b>Dose Used in Risk Assessment, UF</b>                                                                                     | <b>Special FQPA SF* and Level of Concern for Risk Assessment</b>                 | <b>Study and Toxicological Effects</b>                                                                                                                                                                                        |

| Short-, and Intermediate-Term Incidental, Oral (Residential)                                                          | NOAEL = 175 mg/kg/day                                                                                                       | LOC for MOE = 100                                                                | Developmental Toxicity Study - rabbit<br>LOAEL = 350 mg/kg/day based on diarrhea, nasal discharge and death in maternal animals                                                                                               |
| Short-, Intermediate- and Long-Term Dermal (1 - 30 days, 1-6 months, 6 months – lifetime) (Occupational/Residential)  | None                                                                                                                        | None                                                                             | Based on the systemic NOAEL of 1,000 mg/kg/day in the 21 day dermal toxicity study in rabbits, and the lack of concern for developmental and reproductive effects, the quantification of dermal risks is not required.        |
| Short-, Intermediate- and Long-Term Inhalation (1-30 days, 1- 6 months, 6 months-lifetime) (Occupational/Residential) | None                                                                                                                        | None                                                                             | Based on the systemic toxicity NOAEL of 0.36 mg/L (HDT) in the 28-day inhalation toxicity study in rats, and the physical characteristics of the technical (wetcake), the quantification of inhalation risks is not required. |
| Cancer (oral, dermal, inhalation)                                                                                     | <b>Classification:</b> Group E; no evidence of carcinogenicity; risk assessment not required                                |                                                                                  |                                                                                                                                                                                                                               |

### 3.3.6 Other Chemicals

For the purpose this risk assessment, the discussion on “other chemical usage” will be limited to describing the herbicides that glyphosate will be replacing and will be qualitative in nature. In order to thoroughly assess glyphosate’s toxicity as compared to “other chemicals” it would be necessary to do a complete risk assessment on each “other chemical.”

Glyphosate is more environmentally and toxicologically benign than many of the herbicides that it replaces (Cerdeira and Duke, 2006). Peterson and Hulting (2004) compared the ecological risks of glyphosate used in GT wheat with 15 other herbicides used in spring wheat in the northern U.S. Great Plains (Mn, ND, SD, WY, and MT). The herbicides were as follows: 2,4-D, bromoxynil, clodinafop, clopyralid, dicamba, fenoxaprop, flucarbazone, MCPA, metasulfuron, thifensulfuron, tralkoxydim, triallate, triasulfuron, tribenuron, and trifluralin. The ecological risks for the 15 herbicides relative to glyphosate were highly variable, with glyphosate having

less relative risk to non-target terrestrial and aquatic plant life and groundwater than most other active ingredients. The study predicted that glyphosate use in GT crops will be less toxic to terrestrial and aquatic wildlife than several of the herbicides which they replace (Peterson and Hulting, 2004).

The other major ecological concern from glyphosate usage in GT crops is the development of glyphosate resistant weeds. Weeds can develop resistance to herbicides for the following reasons: frequent exposure to a particular herbicide, the spread of naturally resistant weed seeds, and the outcrossing of herbicide-tolerant genes from genetically altered plants to weedy relatives. In the event of glyphosate resistant weeds the management practices suggested are use the following less resistant-prone herbicides recommended for use: paraquat/diquat, MSMA, phenoxy herbicide (e.g., 2,4-D, MCPA, trichlopyr, dicamba), tubulin inhibitors (e.g., benefin, fluchloralin, pendimethalin, ethanlfluralin, trifluralin), triazine (amitrole, atrazine, cyanazine, simazine, trietazine, metribuzin) and/or rare protox herbicides (acifluorfen). These herbicides are more toxic and persistent exerting a greater environmental impact; however, weed management is plant specific. In some cases of multiple herbicide resistance weed management practices are deep tillage (Peterson and Hulting, 2004).

In terms of human health, a qualitative assessment was conducted by comparing oral RfDs for these “other chemicals” (if available) to the proposed oral RfD for glyphosate. Based on the available acute and chronic oral RfDs for the majority of the “other chemicals”, glyphosate’s RfD is higher, therefore, making it more toxicologically benign, compared to the “other chemicals”. The RfDs for the “other chemicals” are presented in table L-15. For further information and references to these RfD values, please see appendix L-5 of this technical report.

**Table L-15. Summary Table of RfDs for “Other Chemicals”**

| <b>Chemical Name</b>              | <b>RfD (oral)</b>                                                                                                                                                                                       |
|-----------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

## 3.4 Risk Characterization

### 3.4.1 Overview

As discussed in section 3.2, the general public may be exposed to herbicides used on GT alfalfa if they consume crops that were grown near GT alfalfa fields. However, in section 3.1, it was demonstrated that the US EPA considers glyphosate to be of low acute toxicity by oral, dermal, and ocular routes of exposure, since all studies are classified as Toxicity Category III or IV. Furthermore, an acute inhalation study was waived by the US EPA because glyphosate is a non-volatile solid and the studies conducted on the end-use product formulation are considered sufficient. In terms of subchronic and chronic toxicity, one of the more consistent effects of exposure to glyphosate is loss of body weight. This observed weight loss may be consistent with experimental data indicating glyphosate's mechanism of action as an uncoupler of oxidative phosphorylation (see section 3.1.2). Other general and non-specific signs of toxicity from subchronic and chronic exposure to glyphosate include changes in liver weight, blood chemistry (may suggests mild liver toxicity), liver pathology, and in pituitary weight (USDA, 2003). Glyphosate is not a carcinogen, however, and has been classified by the US EPA as a Group E carcinogen (evidence of non-carcinogenicity for humans) (US EPA, 2006; 1993).

### 3.4.2 Risk Characterization

To determine if any population subgroup is at risk of adverse effects associated with glyphosate, estimated exposure doses are compared with a health benchmark specific to glyphosate. As discussed in section 3.3, the recommended oral RfD for acute and chronic exposure scenarios for glyphosate is 2 mg/kg of body weight per day. This means that individuals with oral exposure doses equal to or less than 2 mg/kg of body weight per day should not be at risk of adverse effects associated with exposure to glyphosate. The risk metric used to determine if individuals are at risk of adverse effects is called the hazard quotient (HQ). The hazard quotient is the ratio of the estimated exposure dose to the chemical-specific health benchmark (e.g., RfD) (See equation 3.4.2). If the HQ is estimated to be less than 1, no adverse effects are expected as a result of exposure to the chemical of concern. If the HQ is greater than 1, adverse health effects are possible. However, an HQ exceeding 1 does not indicate that adverse effects are certain to occur. Since glyphosate is considered a Group E carcinogen (i.e., signifies non-carcinogenicity in humans) (US EPA, 1993), an analysis of cancer risk was not conducted.

Equation L-14

$$HQ = \frac{Exposure}{RfD}$$

Where:

|          |   |                                            |
|----------|---|--------------------------------------------|
| HQ       | = | Hazard quotient (unitless)                 |
| Exposure | = | Estimated exposure dose (mg/kg BW per day) |
| RfD      | = | Reference dose (mg/kg BW per day)          |

### 3.4.2.1 Risk Characterization for Acute Oral Exposure

Acute exposure estimates for adults (20-39 years), the elderly (70+ years), and infants (under 1 year in age) exposed to glyphosate-contaminated fruits and vegetables were presented in section 3.2. Results are summarized in table L-16 and in worksheet 13 in the calculations spreadsheet submitted with this report. Also, please refer to the calculations worksheet submitted with this report for further explanation of exposure estimate calculations.

**Table L-16. Acute Exposure Estimates by Age Group and Scenario (in mg/kg BW per day)**

| Scenario  | Age Group | Central Estimate | Lower Estimate | Upper Estimate | Worksheet |
|-----------|-----------|------------------|----------------|----------------|-----------|
| Fruit     | Adults    | 2.63E-02         | 0.00E+00       | 1.25E+00       | 1         |
| Fruit     | Elderly   | 4.17E-02         | 1.25E-02       | 4.50E-01       | 2         |
| Fruit     | Infants   | 2.09E-01         | 0.00E+00       | 6.32E+00       | 3         |
| Vegetable | Adults    | 3.18E-01         | 1.85E-01       | 4.61E+00       | 4         |
| Vegetable | Elderly   | 3.66E-01         | 2.22E-01       | 5.11E+00       | 5         |
| Vegetable | Infants   | 6.12E-01         | 0.00E+00       | 1.21E+01       | 6         |

Acute exposure estimates were compared to the acute oral RfD of 2 mg/kg of body weight per day. Results are presented in table L-17. HQs above 1 are presented in bold type. Please refer to the calculations worksheet submitted with this report for further explanation of hazard quotient calculations.

**Table L-17. HQs by Age Group and Scenario**

| Scenario  | Age Group | Central Estimate (in mg/kg BW per day) | Lower Estimate (in mg/kg BW per day) | Upper Estimate (in mg/kg BW per day) | RfD (in mg/kg BW per day) | Worksheet |
|-----------|-----------|----------------------------------------|--------------------------------------|--------------------------------------|---------------------------|-----------|
| Fruit     | Adults    | 0.01                                   | 0.00                                 | 0.62                                 | 2                         | 14        |
| Fruit     | Elderly   | 0.02                                   | 0.01                                 | 0.23                                 | 2                         |           |
| Fruit     | Infants   | 0.10                                   | 0.09                                 | <b>3.16</b>                          | 2                         |           |
| Vegetable | Adults    | 0.16                                   | 0.09                                 | <b>2.30</b>                          | 2                         |           |
| Vegetable | Elderly   | 0.18                                   | 0.11                                 | <b>2.55</b>                          | 2                         |           |
| Vegetable | Infants   | 0.31                                   | 0.00                                 | <b>6.07</b>                          | 2                         |           |

### 3.4.2.2 Risk Characterization for Chronic Oral Exposure

Chronic exposure estimates for adults (20-39 years), the elderly (70+ years), and infants (under 1 year) exposed to glyphosate-contaminated fruits and vegetables were presented in section 3.2. Results are summarized in table L-18 and in worksheet 13 in the calculations spreadsheet submitted with this report. Also, please refer to the calculations worksheet submitted with this report for further explanation of exposure estimate calculations.

**Table L-18. Chronic Exposure Estimates by Age Group and Scenario  
(in mg/kg BW per day)**

| Scenario  | Age Group | Central Estimate | Lower Estimate | Upper Estimate | Worksheet |
|-----------|-----------|------------------|----------------|----------------|-----------|
| Fruit     | Adults    | 1.44E-02         | 0.00E+00       | 6.83E-01       | 7         |
| Fruit     | Elderly   | 2.29E-02         | 6.82E-03       | 2.46E-01       | 8         |
| Fruit     | Infants   | 1.14E-01         | 0.00E+00       | 3.46E+00       | 9         |
| Vegetable | Adults    | 1.74E-01         | 1.01E-01       | 2.52E+00       | 10        |
| Vegetable | Elderly   | 2.00E-01         | 1.22E-01       | 2.80E+00       | 11        |
| Vegetable | Infants   | 3.35E-01         | 0.00E+00       | 6.65E+00       | 12        |

Chronic oral exposure estimates were compared to the chronic oral RfD of 2 mg/kg of body weight per day. Results are presented in table L-19. HQs above 1 are presented in bold type. Please refer to the calculations worksheet submitted with this report for further explanation of hazard quotient calculations.

**Table L-19. HQs by Age Group and Scenario**

| Scenario  | Age Group | Central Estimate<br>(in mg/kg<br>BW per<br>day) | Lower Estimate<br>(in mg/kg<br>BW per<br>day) | Upper Estimate<br>(in mg/kg<br>BW per<br>day) | RfD<br>(in mg/kg<br>BW per<br>day) | Worksheet |

### 3.4.3 Discussion

EPA's (1993) RED for glyphosate included a dietary risk assessment in which it was determined that non-nursing infants were at highest risk of potential adverse effects associated with glyphosate exposure. EPA used tolerance level residues to estimate the Theoretical Maximum Residue Contribution (TMRC) for the overall U.S. population and 22 population subgroups. The TMRC for the U.S. population from food uses of glyphosate was 0.025 mg/kg/day (or 1.2% of the 2 mg/kg/day reference dose). Non-nursing infants less than one year old had a TMRC of 0.058 mg/kg/day (or 2.9% of the reference dose). This analysis was designed as a worst case scenario and assumptions most likely result in an extremely protective estimate of exposure and risk. However, there was little commodity-specific consumption data at the time of the analysis, which may result in a less protective estimate. In its 2006 risk assessment for specific uses of glyphosate on Indian mulberry and dried peas, EPA used a proprietary dietary exposure and risk assessment model, DEEM-FCID™ to complete the dietary analysis for the general public. EPA only conducted a chronic dietary analysis and found that the highest exposed group, also infants under one year of age, was only exposed at 7% of the health benchmark used in the analysis. The results suggested that even the highest exposed group is not at risk of adverse effects (EPA, 2006).

The present analysis considers the possibility that any type of fruit or vegetable could be contaminated by glyphosate. As explained in section 3.2, central, upper, and lower estimates of

consumption rates were used to estimate exposure and risk for adults, infants, and the elderly. It is anticipated that the results of this analysis are highly conservative for several reasons. First, the upper bound exposure and risk estimates are based on fruit and vegetable consumption rates characteristic of the 100<sup>th</sup> percentile of the population. In addition, in assuming a spray drift of one for all scenarios, this analysis assumes that fruits and vegetables will have the same residue of glyphosate as the GT alfalfa will. Application rates are specific to herbicides used to treat GT alfalfa fields, which is not meant for human consumption, as opposed to rates specific to fruits and vegetables. Acute and chronic scenarios assume that fruits and vegetables growing in nearby fields will be contaminated at the same level; however this is a highly conservative and in most cases unlikely scenario.

### 3.5 Summary of Findings

The use of currently registered pesticide products containing glyphosate in accordance with the labeling will not pose unreasonable risks or adverse effects to humans or the environment. It is a violation of federal law for any person to apply a registered pesticide in a manner inconsistent with its label. In general, the herbicidal activity of glyphosate is due primarily to a metabolic pathway that does not occur in humans or other animals, and, thus, this mechanism of action is not directly relevant to the human health risk assessment. The US EPA considers glyphosate to be of low acute toxicity by oral, dermal, and ocular routes of exposure, since all studies are classified as Toxicity Category III or IV. Furthermore, an acute inhalation study was waived by the US EPA because glyphosate is a non-volatile solid and the studies conducted on the end-use product formulation are considered sufficient.

Acute oral exposure estimates from fruit ingestion for adults ranged from zero to 1.25E+00 mg/kg body weight per day. For elderly people, acute oral exposure estimates from fruit ingestion ranged from 1.25E-02 to 4.5E-01 mg/kg body weight per day. For infants, acute oral exposure estimates from fruit ingestion ranged from zero to 6.32E+00 mg/kg bodyweight per day.

Acute oral exposure estimates from vegetable ingestion for adults ranged from 1.85E-01 to 4.61E+00 mg/kg body weight per day. For elderly people, acute oral exposure estimates from vegetable ingestion ranged from 2.22E-01 to 5.11E+00 mg/kg body weight per day. For infants, acute oral exposure estimates from vegetable ingestion ranged from zero to 1.21E+01 mg/kg body weight per day.

Central and lower hazard quotient (HQ) estimates were all under 1, suggesting that the majority of the population is not at risk of adverse health effects associated with acute exposure to glyphosate. Based on upper estimates of exposure, however, infants consuming fruit and all age groups consuming vegetables may be at risk of adverse effects associated with acute exposure to glyphosate. The age group at highest risk is infants under one year of age, which is consistent with US EPA's findings (US EPA, 2006; 1993). The upper estimate HQ for infants with acute exposure to fruit was approximately 3. The upper estimate HQs for all age groups with acute exposure to vegetables ranged from approximately 2 to 6. These results are all over 1, suggesting the potential for adverse health effects associated with glyphosate. It should be noted,

though, that the upper estimates of risk are based on highly conservative fruit and vegetable intake rates; thus it is anticipated that only a very small number of individuals will have this magnitude of exposure and therefore be at this level of risk.

In terms of subchronic and chronic toxicity, one of the more consistent effects of exposure to glyphosate is loss of body weight. This observed weight loss may be consistent with experimental data indicating glyphosate's mechanism of action as an uncoupler of oxidative phosphorylation (see section 3.1.2). Other general and non-specific signs of toxicity from subchronic and chronic exposure to glyphosate include changes in liver weight, blood chemistry (may suggest mild liver toxicity), liver pathology, and in pituitary weight (USDA, 2003). Glyphosate is not a carcinogen, however, and has been classified by the US EPA as a Group E carcinogen (evidence of non-carcinogenicity for humans) (US EPA, 2006; 1993).

Chronic oral exposure estimates from fruit ingestion for adults ranged from zero to  $6.83\text{E-}01$  mg/kg body weight per day. For elderly people, chronic oral exposure estimates from fruit ingestion ranged from  $6.82\text{E-}03$  to  $2.46\text{E-}01$  mg/kg body weight per day. For infants, chronic oral exposure estimates from fruit ingestion ranged from 0 to  $3.46\text{E+}00$  mg/kg body weight per day.

Chronic oral exposure estimates from vegetable ingestion for adults ranged from  $1.01\text{E-}01$  to  $2.52\text{E+}00$  mg/kg body weight per day. For elderly people, chronic oral exposure estimates from vegetable ingestion ranged from  $1.22\text{E-}01$  to  $2.80\text{E+}00$  mg/kg body weight per day. For infants, chronic oral exposure estimates from vegetable ingestion ranged from 0 to  $6.65\text{E+}00$  mg/kg body weight per day.

Central and lower hazard quotient (HQ) estimates were all under 1, suggesting that the majority of the population is not at risk of adverse health effects associated with acute exposure to glyphosate. Based on upper estimates of exposure, however, infants consuming fruit and all age groups consuming vegetables may be at risk of adverse effects associated with chronic exposure to glyphosate. The age group at highest risk is infants under one year of age, which is consistent with US EPA's findings (1993, 2006). The upper estimate HQ for infants with chronic exposure to fruit was approximately 2. The upper estimate HQs for all age groups with chronic exposure to vegetables ranged from approximately 1 to 3. These results are all greater than or equal to one, suggesting the potential for adverse health effects associated with glyphosate. It should be noted, though, that the upper estimates of risk are based on highly conservative fruit and vegetable intake rates; thus it is anticipated that only a very small number of individuals will have this magnitude of exposure and, therefore, be at this level of risk.

## **Appendix L-2. Literature Search**

### **1.0 Literature Search Strategy**

#### **1.1 Purpose**

Primary sources of data were obtained from the following three documents: the United States Environmental Protection Agency (US EPA) 1993 Reregistration Eligibility Decision (RED) document on glyphosate (US EPA, 1993); the U.S. EPA's Glyphosate Human Health Risk Assessment for Proposed Use on Indian Mulberry and Amended Use on Pea, Dry (US EPA, 2006); and the USDA, Forest Service 2003 human health and ecological risk assessment on glyphosate (USDA, 2003). The purpose of this literature search, therefore, was to locate additional references about the health and safety risks from increased glyphosate and other chemical usage on humans (exclusive of field workers). Several DIALOG databases were searched, and Google, and Google Scholar search engines supplemented the DIALOG search. References were selected from the extensive list of literature based on requesting the abstracts and determining if the open literature data were not included in the three primary documents listed below or provided contrary or controversial information to these documents.

The following DIALOG databases will be included in the search:

|                                                 |                                |
|-------------------------------------------------|--------------------------------|
| File 5: BIOSIS                                  | File 6: NTIS                   |
| File 34: SciSearch                              | File 41: Pollution Abstracts   |
| File 40: Enviroline                             | File 72: EMBASE                |
| File 76: Environmental Sciences                 | File 79: Aqualine              |
| File 98: General Science Abstracts              | File 117: Water Resources      |
| Abstracts                                       | File 144: PASCAL               |
| File 154: MEDLINE                               | File 156: ToxFile              |
| File 245: WATERNET™                             | File 250: CAB Abstracts        |
| File 266: Federal Research In Progress (FEDRIP) | File 399: CA SEARCH®: Chemical |
| File 5: BIOSIS                                  | File 6: NTIS                   |
| File 34: SciSearch                              | File 41: Pollution Abstracts   |

Descriptions of these files are available at <http://library.dialog.com/bluesheets/>.

#### **1.2 Scope of Search**

The search will focus on references published after 1990. A reference list with abstracts will be screened for relevance. English language only publications will be retrieved.

### 1.3 Strategy Overview

A list of search parameters is listed below.

### 1.4 Synonyms

- Glyphosate
- Glyphosate, isopropylamine salt
- Glyphosate, sodium salt
- Glyphosate, potassium
- Glyphosate, ammonium
- Glyphosate, sulfosate
- *N*-(phosphonomethyl) glycine
- Roundup®
- Roundup Ultra®
- Honcho®

### 1.5 Keywords

- |                          |                    |
|--------------------------|--------------------|
| • Acute                  | • Incidental       |
| • Alfalfa                | • Ingest*          |
| • Allowable daily intake | • Inhal*           |
| • Cancer*                | • Inhibition       |
| • Carcino*               | • Irritation       |
| • Chronic                | • Leach*           |
| • Crop                   | • Metabo*          |
| • Degradation            | • Mutagen*         |
| • Derma*                 | • Neuro*           |
| • Developmental          | • Non-target crops |
| • Dietary risk           | • Persistence      |
| • Dose                   | • Reproducti*      |
| • Emission               | • Residue          |
| • Endpoint               | • Risk             |
| • Environmental Health   | • Sensitization    |
| • Embryo                 | • Spray drift      |
| • Environmental impacts  | • Subchronic       |
| • Exposure(s)            | • Terato*          |
| • Eye                    | • Tolerance        |
| • Fertility              | • Toxic*           |
| • Health effect(s)       | • Usage patterns   |

- Human health risk

## 1.6 Submission of Citations for Approval

Using reference management software, pooled information obtained from the various bibliographic databases will be screened to remove duplicates. Additionally, ICF will review the list prior to submission and eliminate any irrelevant citations. Information provided to USDA will include the following (when available):

Title. Publication Year.

## 1.7 Literature Search Results:

### TITLES FROM VARIOUS COMBINATIONS OF THE SEARCH SETS

22/6/3 (Item 3 from file: 154)

14946077 PMID: 12507058

An analysis of \*glyphosate\* data from the California Environmental Protection Agency Pesticide Illness Surveillance Program.

\*2002\*

22/6/20 (Item 20 from file: 154)

14535687 PMID: 11890463

Current methods for assessing \*safety\* of genetically modified crops as exemplified by data on \*Roundup\* Ready soybeans.

Jan-Feb \*2002\*

22/6/21 (Item 21 from file: 154)

16416941 PMID: 15929894

Differential effects of \*glyphosate\* and \*roundup\* on \*human\* placental cells and aromatase.

Jun \*2005\*

22/6/27 (Item 27 from file: 50)

0008562363 CAB Accession Number: 20043013531

The effect of spray particle size and distribution on drift and efficacy of herbicides.

Publication Year: 2004

22/6/28 (Item 28 from file: 154)

14263603 PMID: 11564623

An exploratory analysis of the effect of pesticide \*exposure\* on the risk of spontaneous abortion in an Ontario farm population.

Aug \*2001\*

22/6/32 (Item 32 from file: 73)

| Final AR                                                                           | 1.993946622 | lb AI/acre     | Equation        |

Note: The density value came from the product MSDS. There appears to be a typo on this sheet. It was assumed that the density and specific gravity values would be comparable and that the density of Honcho Plus would be comparable to the density of a similar product, Honcho.

## **Appendix M. Health and Safety Risks for Field Workers**

# Health and Safety Risks for Field Workers

## Executive Summary

In an effort to assess the potential health and safety risks from increased glyphosate usage on field workers due to the proposed deregulation of glyphosate-tolerant alfalfa by the U.S. Department of Agriculture (USDA) in 2005, an occupational health risk assessment was conducted for glyphosate usage on glyphosate-tolerant alfalfa. Conservative hazard estimates suggest that workers are not at risk of adverse health effects associated with acute or chronic dermal exposure to glyphosate. More details on the toxicity and risk of glyphosate are discussed in this technical report.

Glyphosate is a broad spectrum herbicide. It is a systemic, post-emergence herbicide widely used on both agricultural commodities and non-agriculture sites. Glyphosate absorbs directly through plant leaves and spreads rapidly throughout the plant. The use of surfactants enables greater leaf penetration. Glyphosate's mode of action is as a potent and specific inhibitor of the enzyme 5-enolpyruvylshikimate 3-phosphate synthase. This enzyme is located in the shikimate pathway and is essential for the biosynthesis of aromatic amino acids and other aromatic compounds in algae, higher plants, bacteria, fungi, and apicomplexan parasites. The shikimate pathway is absent in mammals.

Glyphosate is among the most widely used pesticides by volume in the United States. While additional glyphosate products may be used, five products are recommended for use on glyphosate-tolerant alfalfa. The five herbicides are Monsanto products and include: Honcho®, Honcho Plus®, Roundup Original MAX®, Roundup WeatherMAX®, and Roundup Ultra MAX II®. Glyphosate products can be formulated to have different concentrations of glyphosate acid per gallon of product. To improve handling, performance, and concentration, the glyphosate acid is formulated as a salt compound. The term acid equivalent (a.e.) refers to the weight of the glyphosate acid, which is herbicidally active, while the term active ingredient (a.i.) is the weight of the glyphosate acid plus the salt.

The U.S. Environmental Protection Agency (EPA) and the states (usually that state's agriculture office) register or license pesticides for use in the United States. EPA receives its authority to register pesticides under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA). Glyphosate was registered for use as an herbicide within the United States through EPA. EPA's toxicological database on glyphosate is considered adequate and complete (US EPA, 1993; 2006). Based on these data, glyphosate is considered to be a toxicologically low-risk herbicide (Cerdeira and Duke, 2006). According to the Reregistration Eligibility Decision (RED) document for glyphosate (US EPA, 1993), glyphosate is of relatively low oral and dermal acute toxicity. For this reason, glyphosate has been assigned to Toxicity Categories III and IV for these effects (i.e., Toxicity Category I indicates the highest degree of acute toxicity, and Category IV the lowest). An acute inhalation study was waived by EPA because glyphosate is a non-volatile solid and the studies conducted on the end-use product formulation are considered

sufficient. With regard to subchronic and chronic toxicity, one of the more consistent effects of exposure to glyphosate is loss of body weight. This observed weight loss may be consistent with experimental data indicating glyphosate's mechanism of action. Other general and non-specific signs of toxicity from subchronic and chronic exposure to glyphosate include changes in liver weight, blood chemistry (may suggest mild liver toxicity), liver pathology, and pituitary weight (USDA, 2003). Glyphosate is not considered a carcinogen; it has been classified by EPA as a Group E carcinogen (evidence of non-carcinogenicity for humans) (US EPA, 1993; 2006).

There are two types of worker exposure scenarios assessed in this report. The first are general worker scenarios in which workers have chronic dermal exposure to glyphosate via one of three typical pesticide application methods: directed foliar, broadcast foliar, or aerial. Chronic dermal exposure estimates ranged from 0.9 ppb (i.e.,  $\mu\text{g/kg}$ ) to 160 ppb for directed foliar application, from 1.32 ppb to 302 ppb for broadcast foliar application, and from 0.48 ppb to 160 ppb for aerial application.

Central, lower, and upper bound chronic dermal hazard quotient (HQ) estimates were all under 1, suggesting that workers exposed to herbicides recommended for use on glyphosate-tolerant alfalfa via directed foliar, broadcast foliar, or aerial application methods are not at risk of adverse effects associated with chronic dermal exposure to glyphosate. HQs ranged from 0 to 0.8 for directed foliar application, from 0.001 to 0.15 for broadcast foliar application and from 0 to 0.08 for aerial application. The most exposed workers were those using a broadcast foliar application method. The upper bound HQ was 0.15, approximately 8% of the chronic dermal reference dose (RfD) of 2 mg/kg/day.

In addition to general worker scenarios, accidental exposure scenarios are also assessed in this report. Accidental exposure scenarios result in workers' acute exposure to glyphosate. There are two accidental exposure scenarios assessed in this report, including an accidental spill on the worker's hands or an accidental spill on the worker's legs. Acute dermal exposure estimates from a spill on the worker's hands ranged from 4.44 ppb to 50.5 ppb. Acute dermal exposure estimates from a spill on the worker's legs ranged from 10.9 to 124 ppb.

Central, upper, and lower bound HQs were all under 1, suggesting that workers who accidentally spill herbicides recommended for use on glyphosate-tolerant alfalfa on hands or legs are not at risk of adverse effects associated with acute dermal exposure to glyphosate. HQs for a spill on the hands ranged from 0.002 to 0.025. HQs for a spill on the legs ranged from 0.005 to 0.062. The most exposed workers were those who spilled glyphosate on the legs. The upper bound HQ was 0.06, approximately 3% of the acute dermal RfD of 2 mg/kg/day.

## 1.0 Introduction

In June 2005, the U.S. Department of Agriculture (USDA) approved the use of Roundup Ready® alfalfa, the only commercially available genetically engineered (GE) alfalfa on the market. Roundup Ready® alfalfa is resistant to the herbicide glyphosate. This means that it is able to survive applications of glyphosate, the active ingredient (a.i.) in the Monsanto Company's trademark herbicide, Roundup®. Monsanto produced this glyphosate-tolerant (GT) alfalfa in partnership with the largest alfalfa seed company, Forage Genetics International (FGI). The transgene responsible for glyphosate tolerance was first introduced in soybeans in 1996 and has since been commercialized in several other crops (e.g., corn, canola, and cotton). In order to determine health and safety risks to field workers in contact with GT alfalfa, an occupational risk assessment must consider the toxicology and exposure potential associated with herbicides containing glyphosate that may be used on the crop. In addition, the assessment should consider risks associated with the gene product and the conventional crop (i.e., alfalfa).

### 1.1 Herbicides

There are several herbicide products containing glyphosate that are recommended for use on GT alfalfa. These products include: Roundup Original Max®, Roundup Weather Max®, and Roundup Ultra Max II® (Monsanto, 2008). According to Greenbook, an online database that partners with chemical manufacturers such as Monsanto to provide information about agricultural products, Honcho® and Honcho Plus® are also recommended for use on GT alfalfa (Greenbook, 2008). Each of these products contains between 41 and 48% glyphosate (Monsanto, 2004; 2007b; 2007d; 2007f; 2007e). Consideration of other ingredients in the end use products (EUPs) is beyond the scope of this exposure assessment. For purposes of this analysis, exposure estimates of glyphosate are presented as opposed to exposure estimates of the EUPs because toxicological data required to assess risk were not available for the EUPs at the time of this analysis.

Glyphosate use increased more than six-fold between 1992 and 2002, to become the most used herbicide in the United States. In 1997, it was listed on the Agency of Toxic Substances and Disease Registry's (ATSDR) 100 most frequently released substances (ATSDR, 1997). A controversy exists over whether glyphosate usage has increased as a result of GT crops. A few studies have claimed that the volume of herbicide use is greater due to GT crops (Benbrook, 2001; 2003; 2004). On the other hand, others, such as Heimlich et al. (2000) have indicated there has not been a significant increase in the amount of glyphosate usage since emergence of GT crops. Heimlich et al. (2000) noted that using glyphosate has resulted in the replacement of herbicides that are at least three times as toxic and persist almost twice as long as glyphosate. For example, in cotton and soybean fields for the most part, several herbicides were replaced by glyphosate (million pounds reduction): bentazon (-4.4), disodium methanearsenate (DSMA; -0.8), fluometuron (-4.5), imazethapyr (-1.0), metribuzin (-1.5), methylarsonic acid sodium salt (MSMA) (-1.7), paraquat (-2.9), pendimethalin (-14.0), sethoxydim (-1.1), and trifluralin (-13.0). Furthermore, prior to 2002, metolachlor, which accounted for 67 million pounds of herbicide used in 1997, was voluntarily withdrawn from the market prior to 2002. Glyphosate was adopted on many soybean acres that were previously treated with metolachlor. Cyanazine,

which accounted for 20 million pounds of herbicide used in 1997, was also voluntarily withdrawn from the market prior to 2002 and replaced by glyphosate for use on cotton and corn. In addition to glyphosate, corn producers replaced cyanazine with the herbicides mesotrione, rimsulfuron, and simazine (Gianessi and Reigner, 2006).

Additionally, Trewavas and Leaver (2001) conducted an analysis which revealed that 3.27 million kg of other herbicides have been replaced with 2.45 million kg of glyphosate in soybean fields in the United States. Carpenter and Gianessi (2003) concluded that the introduction of GT soybeans has resulted in a decrease in the total volume of herbicides used. Gianessi (2005) estimates that averaged over all GT crops, GT technology has reduced herbicide use by 17 million kg/year in the United States. However, Gianessi's (2005) calculations indicate that if GT sugar beets were adopted, reduction in herbicide use would not be as great as for combined GT crops, because the herbicides used now in non-transgenic sugar beets are mainly low use rate compounds in the United States.

Biomonitoring studies confirm that agricultural workers who apply glyphosate to crops internalize some of the chemical (Curwin et al., 2007; Mandel et al., 2005). EPA (1993) determined in its RED for glyphosate that the chemical may be classified as either a Category III (i.e., slightly toxic; slightly irritating) or Category IV (i.e., practically non-toxic; not an irritant) toxicant. Toxicity and occupational exposure data exist for glyphosate, and the remainder of this occupational assessment utilizes these data to estimate exposure and risk to field workers.

## 1.2 Gene Product

The expressed gene product in GT alfalfa is a protein, 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS), derived from a soil bacterium, *Agrobacterium* sp. CP4 strain, thus called CP4 EPSPS. The protein is a single polypeptide that is 455 amino acids long and structurally and functionally similar to the native plant EPSPS enzymes. The herbicide glyphosate inhibits an essential step in aromatic amine synthesis in plants. The CP4 EPSPS protein is not inhibited by the herbicide glyphosate; thus any plant with the protein is resistant to glyphosate application.

The U.S. Food and Drug Administration (FDA), the lead U.S. regulatory agency for review of the food and feed safety of GE crops, completed a voluntary consultation with FGI and Monsanto in 2004 regarding the safety of GT alfalfa (US FDA, 2004b). The FDA (2004b) made the following assertions: the soil bacterium used to create GT alfalfa is not a known allergen or pathogen; the CP4 EPSPS gene and protein lack structural similarities to any allergen; the CP4 EPSPS protein is only a small portion of alfalfa; and while acute toxicity in mice was observed, allergenic responses associated with GT crops have not been reported by farm workers or members of the general population since the commercialization of these crops in 1996. FDA (2004b) did not review studies on dermal or inhalation toxicity of the CP4 EPSPS gene or protein, nor were any available at the time of this analysis.

## 1.3 Conventional Crop

Conventional alfalfa has been used for animal feed for decades. Alfalfa is also consumed by humans (e.g., sprouts, dietary supplements, and herbal teas). Pollen from alfalfa may be a minor

contributor to some respiratory allergic diseases such as asthma, but the risk to human health is minimal. In addition, alfalfa sprouts have been the source of several foodborne outbreaks due to bacterial contamination (US FDA, 1999). Epidemiological investigations suggest that seeds are the likely source in most, if not all, sprout-associated illness outbreaks. Seeds grown for sprouts have more stringent restrictions for chemical applications during growing since the chemicals must be evaluated as food residues. FDA considers GT alfalfa not materially different from conventional alfalfa; therefore it is permitted for human consumption (US FDA, 2004a). However, Monsanto does not allow GT alfalfa to be planted for sprouts (Hubbard, 2008).

#### 1.4 Methodology

The toxicological literature suggests that exposure to the herbicide glyphosate is of greater health concern than is exposure to the gene product or alfalfa itself. Thus, the remainder of this analysis focuses on the chemical and physical properties of glyphosate and the toxicological data on glyphosate. These data, in combination with data specific to the occupational scenarios, are used to conduct an occupational risk assessment for workers exposed to glyphosate. The result of the assessment is an estimate of potential risks associated with occupational exposures to glyphosate due to increased use of glyphosate and deregulation of GT alfalfa.

To support the occupational assessment, literature searches of glyphosate toxicity and exposure were conducted in the open literature using the literature search strategy presented in appendix M-2 of this technical report. This occupational assessment is not a comprehensive summary of all of the available information and does not cite all of the available literature. As USDA (2003) determined, an all inclusive and detailed review of all of the available literature would tend to obscure rather than inform. Therefore, this document relies on the information that is likely to impact the risk assessment. Primary sources of data were obtained from the following three documents: EPA's (1993) RED on glyphosate, EPA's (2006) Glyphosate Human Health Risk Assessment for Proposed Use on Indian Mulberry and Amended Use on Pea, Dry, and USDA's (2003) human health and ecological risk assessment on glyphosate.

Additionally, for the exposure assessment, the application rate of glyphosate on GT alfalfa was determined by collecting the use rates on GT alfalfa from labels of the five products recommended for use on GT alfalfa mentioned previously. It can be expected that other formulations for glyphosate herbicide could and may be used on GT alfalfa. However, this analysis focuses only on the products recommended for use on GT alfalfa.

## 2.0 Overview of Glyphosate

### 2.1 Glyphosate

Glyphosate is a systemic, post-emergence herbicide widely used on both agricultural commodities (food uses) and non-agriculture sites. Glyphosate salts serve as the source of the active ingredient *N*-(phosphonomethyl)glycine. Several salts of glyphosate with different counter cations are currently marketed. Each salt has a different “glyphosate equivalent”, which is defined as the ratio of the molecular weight of *N*-(phosphonomethyl)-glycine to the molecular weight of the salt. While GT alfalfa could tolerate other herbicides formulated with glyphosate, there are five glyphosate herbicides recommended for use on GT alfalfa. These end use products (EUPs) are presented in table M-1.

**Table M-1. End Use Products Approved for Use on Glyphosate-Tolerant Alfalfa**

| Product Name          | % Salt | Glyphosate salt CAS No.           | US EPA PC Code | Surfactant                                           | Manufacture     |
|-----------------------|--------|-----------------------------------|----------------|------------------------------------------------------|-----------------|
| Honcho®               | 41     | Isopropylamine<br>CAS: 38641-94-0 | 103601         | Alkyl Tallow<br>Ethoxylated Amines<br>CAS 61791-26-2 | Monsanto, 2007b |
| Honcho Plus®          | 41     | Isopropylamine<br>CAS: 38641-94-0 | 103601         | Trade Secret                                         | Monsanto, 2007d |
| Roundup Original MAX® | 48.7   | Potassium<br>CAS: 70901-12-1      | 103613         | Trade Secret                                         | Monsanto, 2007e |
| Roundup WeatherMAX®   | 48.8   | Potassium<br>CAS: 70901-12-1      | 103613         | Trade Secret                                         | Monsanto, 2007f |
| Roundup Ultra MAX II® | 48.8   | Potassium<br>CAS: 70901-12-1      | 103613         | Trade Secret                                         | Monsanto, 2004  |

The Honcho® and Honcho Plus® products contain 41% of the isopropylamine (IPA) salt of glyphosate, equivalent to 3 pounds of glyphosate acid equivalent per gallon or 356 grams of a.e. per liter.<sup>47</sup> The product is to be applied as over-the-top (spot treatment; broadcast ground application) for pre-plant, preemergence, and post-emergence uses. The maximum total application rate is 7.98 pounds of glyphosate a.i. per acre per year or 2.6 gallons of product per acre, and the single use maximum application rate is 1.99 pounds of glyphosate a.i. per acre (rounded to 2 pounds of glyphosate a.i. per acre; 1.55 pounds of glyphosate a.e.). Further information regarding application rates is available in section 3.2.2 and in appendix M-4 of this technical report. The minimum reapplication interval is 7 days.

The Roundup Ready Original MAX®, Roundup WeatherMAX®, and Roundup Ultra MAX II® products contain 48.8% of the phosphate salt of glyphosate, equivalent to 4.5 pounds of glyphosate a.e. per gallon or 540 grams per liter. The product is to be applied as over-the-top (spot treatment; broadcast ground application) for pre-plant, preemergence, and post-emergence uses. The maximum total application rate is 7.32 glyphosate pounds a.i. per acre per year or 2.4 gallons of product per acre. The single use maximum application rate is 1.90 pounds of glyphosate a.i. per acre. Further information regarding application rates is available in section 3.2.2 and in appendix M-4 of this technical report. The minimum reapplication interval is 7 days.

<sup>47</sup> In this technical report, the term a.e. refers to the acid equivalent or weight of the glyphosate acid, which is herbicidally active. The term a.i. is the weight of the glyphosate acid plus the salt.

### 2.1.1 Structure and Nomenclature

Glyphosate is a substituted glycine, the simplest amino acid. The glyphosate molecule has a methylphosphono group bonded to the nitrogen atom of the amino group of glycine, as denoted in figure M-1 below.

**Figure M-1: Glyphosate molecular structure**

Glyphosate's structure and nomenclature are presented in table M-2 below.

**Table M-2. Glyphosate Structure and Nomenclature**

| Property                                               | Value                                           | Source             |
|--------------------------------------------------------|-------------------------------------------------|--------------------|

## 2.2 Summary of Findings

Glyphosate is a systemic, post-emergence herbicide widely used on both agricultural commodities (food uses) and non-agriculture sites. Glyphosate salts serve as the source of the a.i. *N*-(phosphonomethyl)glycine. Several salts of glyphosate with different counter cations are currently marketed. At ambient temperatures, glyphosate is a white crystalline substance that is not volatile with high water solubility. In the crystalline form, glyphosate has both positive and negative regions of charge. These dipolar ion species are sometimes referred to as a zwitterion. In aqueous solutions, the hydrogen atoms of the carboxylic acid (COOH) and phosphate (PO<sub>2</sub>H<sub>2</sub>) groups may be associated or dissociated depending on the pH of the solution. These dipolar ion species are the regions expected to bond to carbon-containing molecules in the soil. Glyphosate is in a liquid form for herbicide formulations; generally, the composition of the herbicide is considered trade secret. One formulation of glyphosate, Honcho®, has a tallow amine surfactant (Monsanto, 2007b). This and other surfactants are added to the herbicide formulations to increase leaf penetration.

## 3.0 Occupational Risk Assessment

This occupational risk assessment focuses on risks associated with exposure to herbicides recommended for use on GT alfalfa, all of which contain the active ingredient glyphosate. The risk assessment is presented in four sections, including a hazard identification section in which toxicological data on glyphosate are reviewed and summarized, an exposure assessment section in which worker exposure estimates are presented, a dose-response assessment section in which health benchmarks for glyphosate are reviewed and recommended for different exposure scenarios, and finally a risk characterization section in which worker exposure estimates are compared to health benchmarks to determine the potential for adverse health effects associated with occupational exposures to glyphosate.

### 3.1 Hazard Identification

#### 3.1.1 Overview

According to EPA, the existing toxicity database for glyphosate is complete and without data gaps. There is high confidence in the quality of the existing studies and the reliability of the toxicity endpoints identified for use in risk assessments (US EPA, 1993; 2006). In general, the herbicidal activity of glyphosate is due primarily to a metabolic pathway that does not occur in humans or other animals. Thus, this mechanism of action is not directly relevant to the occupational health risk assessment. However, there remains some uncertainty regarding glyphosate's mechanism of action in humans or experimental animals. Nonetheless, EPA considers glyphosate to be of low acute toxicity by oral, dermal, and ocular routes of exposure, since all studies are classified as Toxicity Category III or IV. Furthermore, an acute inhalation study was waived by EPA because glyphosate is a non-volatile solid and the studies conducted on the end-use product formulation are considered sufficient (US EPA, 1993; 2006).

Glyphosate's toxicity database and its mechanism of action are discussed in greater detail in the following sections. Additionally, a summary table of the toxicology studies included in the USDA (2003) and EPA (1993) documents is included in appendix M-3 of this technical report.

#### 3.1.2 Mechanisms of Action

In plants, glyphosate is a potent and specific inhibitor of the enzyme 5-enolpyruvylshikimate 3-phosphate synthase (EPSPS) in plants. EPSPS is the sixth enzyme on the shikimate pathway and it is essential for the biosynthesis of aromatic amino acids and other aromatic compounds in algae, higher plants, bacteria, fungi, and apicomplexan parasites. However, this metabolic pathway does not exist in humans or other animals (USDA, 2003; US EPA 1993).

While its mechanism of action in plants is well understood, not much is known about glyphosate's ability to cause toxic effects in humans or experimental animals. Corrosive effects on the gastric mucosa, as well as other tissues, are a consistent response following acute oral exposure to high doses of glyphosate or polyethoxylated tallow amine (POEA), a surfactant included in some glyphosate formulations. However, it is speculated that the biochemical pathway leading to mucosal effects differs for each glyphosate and POEA. At present, there are

two proposed biochemical mechanisms of action in humans for glyphosate: uncoupling of oxidative phosphorylation, and inhibition of hepatic mixed function oxidases (USDA, 2003).

Oxidative phosphorylation is a process where nutrients are oxidized to yield metabolic energy which is then transferred to high-energy phosphate bonds and stored. Glyphosate appears to be an uncoupler of oxidative phosphorylation, based on the results of a series of experiments using rat liver mitochondria that was exposed to glyphosate (USDA, 2003). When glyphosate uncouples this process, the result is a loss of energy and eventually death. Symptoms such as increased heart and respiratory rate, labored breathing, profuse sweating, fever, metabolic acidosis, and weight loss may occur in response to the uncoupling of oxidative phosphorylation. Uncoupling of this process has been seen after experimental animals were given intraperitoneal doses as low as 15 mg/kg. However, it has not been determined if interrupting this process plays a major role in acute exposures (USDA, 2003).

Inhibition of hepatic mixed-function oxidases may also account for some of the toxic effects observed following glyphosate exposure. Hepatic mixed-function enzymes are comprised of various isozymes of cytochrome P-450, which is involved in the metabolism of a variety of endogenous compounds as well as xenobiotics. In a study by Hietanen et al. (1983), a decrease in hepatic mixed-function oxidase activity was observed in rats after a 500 mg/kg/day dose of glyphosate for four days followed by doses of 300 mg/kg/day for six days. While this decrease in hepatic mixed-function oxidase activity is only indicative of cytochrome P-450 inhibition, it has been suggested that this effect may be due to glyphosate's inhibition of cytochrome P-450, since glyphosate has caused inhibition in plants (USDA, 2003).

### 3.1.3 *Kinetics and Metabolism*

The residue of concern for risk assessment purposes is glyphosate *per se*. Glyphosate's only known metabolite, aminomethylphosphonate (AMPA; see figure M-2), is not included in either the tolerance expression or the risk assessment (US EPA, 2006). While AMPA is a common environmental metabolite, only trace amounts of it are formed in mammals and the remainder is excreted unchanged. For this reason, direct exposures to AMPA, as an endogenous metabolite in animals, are encompassed by the existing toxicity data on glyphosate.

**Figure M-2: Chemical structure of AMPA**

Since glyphosate is eliminated rapidly from the body and shows a lack of degradation into toxic metabolites, dose levels expressed in mg/kg/day display analogous effects over broad periods of exposure (USDA, 2003). For the general public, the majority of exposures to glyphosate are via the oral and dermal route. Select results from both oral and dermal absorption studies are discussed below.

According to experimental studies, glyphosate is not completely absorbed following oral administration. Much of the reviewed literature has revealed that only about 30% of glyphosate is absorbed from the gastrointestinal tract after oral exposure (USDA, 2003). One metabolism study available at the time of the 1993 reregistration of glyphosate involved a single or repeated dose of radiolabeled  $^{14}\text{C}$ -glyphosate administered orally to Sprague-Dawley rats. Of this dose, 30-36% was absorbed. Less than 0.27% was eliminated as  $\text{CO}_2$ , 97.5% was excreted in the urine and feces as the parent compound, and 0.4-0.7% was excreted in the urine and feces as AMPA. Repeated dosing did not change the metabolism significantly (US EPA, 1993).

Furthermore, studies conducted by Davies (1996e), indicate that the majority of unabsorbed glyphosate remains in the gastrointestinal tract, while the absorbed glyphosate is widely distributed throughout the body. The highest concentrations of glyphosate are found in the bone relative to other tissues, although glyphosate does not concentrate significantly or persist in any tissue (US EPA, 1993). A second metabolism study available at the time of the 1993 reregistration of glyphosate involved dosing Sprague-Dawley rats with a single 1150 mg/kg intraperitoneal injection of radiolabeled  $^{14}\text{C}$ -glyphosate. Approximately 0.0044-0.0072% of this dose was found in the bone marrow after 30 minutes. The half-life of glyphosate in bone marrow was 7.6 hours for males and 4.2 hours for females. In addition, the study determined that the half life of glyphosate in plasma was 1 hour for both sexes (US EPA, 1993).

Glyphosate is also poorly absorbed following dermal applications, as indicated by two dermal absorption studies performed by Wester et al. (1991; 1996). One of the studies was performed using skin from human cadavers. In this study, the cadaver skin was exposed to undiluted glyphosate herbicide formulations (i.e., containing more of the POEA surfactant) for eight hours, and diluted formulations for up to 16 hours. Based on 16-hours of exposure to the diluted formulations, first-order dermal absorption rates ranged from  $1.3 \times 10^{-4}$  to  $1.0 \times 10^{-3} \text{ h}^{-1}$  (average:  $4.1 \times 10^{-4} \text{ h}^{-1}$ ), while first-order dermal absorption rates after 8-hours of exposure to the more

concentrated formulation ranged from  $7.5 \times 10^{-5}$  to  $5.1 \times 10^{-4}$  (USDA, 2003). The results of this study indicate that glyphosate containing the POEA surfactant does not absorb more rapidly than a glyphosate formulation with a less concentrated solution of surfactant. A second study was performed on monkeys and found that after 12 hours of exposure, approximately 1.5% of the glyphosate was absorbed, which is equivalent to a first-order dermal absorption rate of  $1.3 \times 10^{-3} \text{ hour}^{-1}$  (Wester, 1991). Wester's dermal absorption rates are used later in the occupational exposure assessment. Wester's measurements and methods are consistent with other derived values and standard methods used to estimate first-order dermal absorption rates (USDA, 2003).

#### *3.1.4 Acute Systemic Toxicology*

As is common with most chemicals, acute exposure to glyphosate and its commercial formulation may be toxic at sufficiently high levels. An experiment performed by Williams et al. (2000) on rats and mice found that acute oral  $\text{LD}_{50}$  values (the lethal dosage required to kill 50 percent of a population of test animals) of glyphosate range from approximately 2,000 to 6,000 mg/kg and acute oral intraperitoneal  $\text{LD}_{50}$  values, which are about 10 times lower in value, range from 134 to 234 mg/kg (USDA, 2003). Additionally, systemic differences in toxicity do not appear to exist among species when doses of glyphosate are expressed in units of mg/kg body weight.

Documentation suggests that exposure to glyphosate with a POEA surfactant is a common means of suicide, and this fact can be used to make a determination about its effects on humans. In an analysis of suicide cases in Taiwan, doses of glyphosate/surfactant formulations in the range of  $330 \pm 42 \text{ mL}$  were associated with fatalities and the survivors were correlated with doses of  $122 \pm 12 \text{ mL}$ . Gastrointestinal effects (vomiting, abdominal pain, diarrhea), irritation, congestion, or other forms of damage to the respiratory tract, pulmonary edema, decreased urinary output sometimes accompanied by acute renal tubular necrosis, hypotension, metabolic acidosis, and electrolyte imbalances, probably secondary to the gastrointestinal and renal effects, are seen in human cases of glyphosate/surfactant exposure. It is speculated that the POEA surfactant component in the glyphosate formulations may be the dominant contributing factor leading to the effects seen in these suicide cases (USDA, 2003).

This occupational risk assessment only considers the increased use of glyphosate as an herbicide. According to EPA, glyphosate is considered to be of low acute toxicity by oral, dermal, and ocular routes of exposure, since all studies are in Toxicity Category III or IV. Toxicity Categories III and IV denote slight to practically non-toxic effects, respectively. Furthermore, an acute inhalation study was waived by EPA because glyphosate is a non-volatile solid and the studies conducted on the end-use product formulation are considered sufficient (US EPA, 2006; 1993). Additionally, according to the World Health Organization (WHO) (1996), glyphosate has been classified as unlikely to present an acute hazard in normal use. EPA's acute toxicity profile for glyphosate is presented in table M-4.

**Table M-4. Acute Toxicity Profile of Glyphosate (US EPA, 2006)**

| US EPA Guideline No. | Study Type              | MRID(s)  | Results                                                                   | Toxicity Category |
|----------------------|-------------------------|----------|---------------------------------------------------------------------------|-------------------|
| 870.1100             | Acute oral              | 41400601 | LD <sub>50</sub> > 5,000 mg/kg                                            | IV                |
| 870.1200             | Acute dermal            | 41400602 | LD <sub>50</sub> > 5,000 mg/kg                                            | IV                |

### 3.1.5 General Subchronic and Chronic Systemic Toxicology

Loss of body weight is one of the more consistent signs of subchronic or chronic exposure to glyphosate. This effect has been noted in mice, rats, dogs, and rabbits. Observed weight loss is consistent with experimental data indicating that glyphosate may be an uncoupler of oxidative phosphorylation. Additionally, the loss of body weight observed was not associated with a significant decrease in food consumption. Other general and non-specific signs of toxicity include liver weight, blood chemistry (may suggest mild liver toxicity), liver pathology, and changes in pituitary weight (USDA, 2003). The results of several subchronic and chronic toxicity studies are presented in table M-5 and discussed in the subsequent paragraphs.

**Table M-5. Subchronic and Chronic Toxicity Profile of Glyphosate (US EPA, 2006)**

| US EPA Guideline No./ Study Type                                            | Results                                                                                                                                                                                       |

One of the studies included in table M-5 is a 90-day oral toxicity study in rats exposed to AMPA. As noted in the table and previously discussed, AMPA is a metabolite of glyphosate, and in soil and environmental water samples it is found more regularly than glyphosate. AMPA is considered slightly more toxic than glyphosate. However, while AMPA is a common environmental metabolite, only trace amounts of it are formed in mammals, with the remainder being excreted unchanged. For this reason, direct exposures to AMPA, as an endogenous metabolite in animals, are encompassed by the existing toxicity data on glyphosate. For further

discussion of the occurrence of environmental concentrations of glyphosate or its metabolite AMPA, see the technical report: *Potential Impacts to Wildlife, Amphibians, Plants, and Ecosystems from Increased Glyphosate and Other Chemical Usage* (appendix N).

Two subchronic feeding studies in rodents conducted at the time of the 1993 RED showed effects in the blood and pancreas. In the first 90-day feeding study, Sprague-Dawley rats were fed glyphosate for three months in doses equivalent to 0, 63, 317, or 1,267 mg/kg/day for males and 0, 84, 404, or 1,623 mg/kg/day for females. Males and females in all treated groups showed increased serum phosphorus and potassium. The mid-dose group had increased serum glucose. Likewise, the high-dose had increased serum glucose, blood urea nitrogen, and serum alkaline phosphatase and an increased occurrence of pancreatic lesions. EPA determined that based on these results, the no observed effect level (NOEL) should be <63 mg/kg/day for males and <84 mg/kg/day for females. However, these results were considered only possibly treatment related, and the NOEL dose for each sex was not determined definitively (US EPA, 1993).

In the second subchronic feeding study, CD-1 mice were fed diets containing 0, 250, 500 or 2,500 mg/kg/day of glyphosate for 90 days. The risk assessment parameters were set based on decreases of body weight gains in the high-dose males and females of about 24% and 18%, respectively. Based on the observed decrease in body weight gain, the NOEL recommended for both sexes is 500 mg/kg/day and the recommended lowest observed effect level (LOEL) is 2,500 mg/kg/day (US EPA, 1993).

### 3.1.6 Effects on Nervous System

There was no evidence of neurotoxicity in any of the toxicology studies conducted and there are no data requirements for neurotoxicity studies. Moreover, analysis of detailed literature on health outcomes of accidental and intentional gross over-exposures, such as suicides, to glyphosate or its commercial formulations also do not implicate it in neurotoxicity effects. The weight of evidence suggests that any neurological symptoms associated with glyphosate exposures were secondary to other toxic effects and cannot be attributed to exposures directly (USDA, 2003). Based on weight of evidence considerations, EPA determined that it is not necessary to conduct a developmental neurotoxicity study with glyphosate to evaluate the potential for developmental neurotoxic effects (US EPA, 1993; 2006; USDA, 2003).

A selection of relevant neurotoxicity studies are discussed in the following paragraphs. Many of the other neurological studies conducted presented results that were not considered scientifically robust and, therefore, are not discussed in further detail in this section (USDA, 2003).

Glyphosate has been tested for neurotoxicity in rats after both acute and subchronic exposures, and has been tested for delayed neurotoxicity in hens (USDA, 2003). In an acute study, 10 male and 10 female rats were given doses of 50, 100, or 200 mg of glyphosate a.e./kg and were observed for 2 weeks. In a subchronic study, 12 female and 12 male rats were exposed to glyphosate in their diet at concentrations of 2,000, 8,000, or 20,000 ppm for 13 weeks. In both studies, glyphosate was negative for signs of neurotoxicity. In a third study, twenty hens were given a single gavage dose of 2,000 mg/kg of glyphosate. A slight decrease in brain AchE

activity occurred, but there were no signs of delayed motor ataxia or neuropathology (USDA, 2003).

An additional subchronic study in rats and mice, preformed by the National Toxicology Program (NTP) (1992), suggests that glyphosate may produce histological changes in the salivary glands in both organisms. While glyphosate may produce changes of the salivary gland by acting through an adrenergic pathway or by producing an adrenergic-mediated stimulation through some indirect mechanism, the mechanism causing this effect is not understood clearly and no signs of neurotoxicity were observed (USDA, 2003).

In an investigation of the effects of glyphosate on sensory mechanisms, a 1 mM or 10 mM dose of glyphosate was applied to the tongue of anesthetized gerbils. As a result, their taste tester response (to table salt, sugar, and acids) decreased. Due to the possibility of outside variables affecting experimentation, these results were not classified clearly as a glyphosate-induced neurological effect (USDA, 2003).

### 3.1.7 Effects on Immune System

Glyphosate has been tested for effects on the immune system in humans and experimental animals, in both *in vivo* and *in vitro* studies. In an *in vivo* study preformed by Blakley (1997), mice were exposed to glyphosate in their drinking water, at concentrations of 0, 0.35, 0.70, or 1.05 percent, for 26 days. Their antibody immune response was evaluated using sheep red blood cell challenge. The study found that the response in exposed mice did not differ from that of the unexposed mice (controls). Additionally, an *in vitro* study using human immunocompetent cells also indicated that glyphosate at concentrations ranging from 0.01 to 10  $\mu$ moles had no effect on the immune system (Flaherty et al., 1991). Furthermore, there is also no evidence to suggest that glyphosate causes dermal sensitization or morphologic abnormalities, in experimental animals, which could implicate an effect on the immune system (USDA, 2003).

In studies performed on humans, there has been no confirmation that glyphosate directly causes photoirritation, photosensitization, or allergic responses (Maibach, 1986; Jauhiainen et al., 1991; Williams et al., 2000). In a study by Maibach (1986), a group of volunteers were exposed to Roundup® via direct dermal application and no significant responses were observed.

### 3.1.8 Effects of Endocrine Function

Of the specific tests conducted to determine potential effects of glyphosate on the endocrine system, none have reported any potential estrogen, androgen, and/or thyroid mediated toxicity resulting from exposure to glyphosate (US EPA, 2006; USDA, 2003).

Glyphosate was inactive as an estrogen receptor agonist in MCF-7 human breast cancer cells (Lin and Garry, 2000) and in yeast and trout hepatocyte assays (Petit et al, 1997). Additionally, in another study, the steroidogenic acute regulatory (StAR) protein, which mediates the rate-limiting step in the mitochondrial synthesis of steroid hormones, was not disrupted by glyphosate. Therefore, glyphosate did not inhibit steroid synthesis in MA-10 mouse Leydig tumor cells. In a third test, glyphosate, with surfactant, was found to inhibit steroid synthesis. It should be noted that all of these studies were conducted *in vitro* and were used to assess whether

a plausible biological mechanism exists for glyphosate to act as an endocrine disruptor (USDA, 2003).

### *3.1.9 Reproductive and Teratogenic Effects*

Exposure to glyphosate has been evaluated for its effects on reproduction and ability to cause birth defects (i.e., teratogenic effects). Most of the literature indicates that glyphosate does not directly cause reproductive or teratogenic effects (US EPA, 1993; 2006; USDA, 2003). Four studies on the maternal, reproductive, and developmental toxicity of glyphosate were submitted for reregistration of glyphosate in 1993 (US EPA, 1993; 2006). The studies are discussed in the following paragraphs and the results are presented in table M-6.

In the first study, Charles River COBS CD rats were dosed with 0, 300, 1,000, or 3,500 mg/kg/day of glyphosate by gavage during gestation days six through 19. The high dose dams showed signs of diarrhea, decreased mean body weight, breathing rattles, inactivity, red matter around the nose, mouth, forelimbs, and dorsal head, decreases in total implantations per dam and fetuses per dam, and mortality. Developmental effects were also only seen in the high-dose group and included increased litter numbers and fetuses with unossified sternebrae and decreased mean fetal body weights. Based on these results, the recommended maternal and developmental toxicity no observed adverse effect level (NOAEL) and the lowest observed adverse effect level (LOAEL) are 1,000 mg/kg/day and 3,500 mg/kg/day, respectively (US EPA, 1993; 2006; USDA, 2003).

In a second developmental and maternal toxicity study, Dutch Belted rabbits administered 0, 75, 175, or 350 mg/kg/day during gestation days six through 27 showed treatment-related findings at the highest dose only. These effects included diarrhea, nasal discharge, and death. There were no developmental effects observed, which could be attributable to the high maternal mortality level (62.5% at the highest dose). The NOAEL and LOAEL for maternal toxicity are 175 mg/kg/day and 350 mg/kg/day, respectively (US EPA, 1993; 2006; USDA, 2003).

In a three-generation reproduction study on male and female Sprague-Dawley rats administered 0, 3, 10, or 30 mg/kg/day of glyphosate continuously through diet, increased incidence of focal tubular dilation of the kidney was seen in the high-dose male third generation pups. The recommended NOEL for reproductive toxicity is  $\geq 30$  mg/kg/day. The recommended developmental toxicity NOAEL and LOAEL are 10 mg/kg/day and 30 mg/kg/day, respectively (US EPA, 1993; 2006; USDA, 2003).

A two-generation reproduction study showed treatment-related effects at the high dose when Sprague-Dawley rats were administered 0, 100, 500, or 1,500 mg/kg/day of glyphosate continuously through the diet. These effects included soft stools in the F<sub>0</sub> and F<sub>1</sub> generations, decreased food consumption and body weight gain in the F<sub>0</sub> and F<sub>1</sub> generations during the growth period, and decreased body weight gain in the F<sub>1</sub> and F<sub>2</sub> generations during the second and third week of lactation. Based on these effects, the recommended reproductive and developmental NOEL is 500 mg/kg/day and the recommended reproductive and development LOEL is 1,500 mg/kg/day (US EPA 1993; 2006).

**Table M-6. Reproductive and Teratogenic Toxicity Profile for Glyphosate (US EPA, 2006)**

| Study Type                                                         | Results                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |

Additional studies conducted to evaluate the reproductive and teratogenic effects of glyphosate, include subchronic and chronic exposure studies, which attempted to examine the impacts of glyphosate exposure on morphology of reproductive organs, mammary glands, and endocrine glands (including the testis, ovary, pituitary, thyroid, adrenal, pancreas, parathyroid, and thymus). In both subchronic and chronic studies, no treatment-related effects on reproductive organs or endocrine glands were observed at or below the maximally tolerated dose of 20,000 ppm in the diet in the chronic study (Stout and Ruecker, 1990) and 50,000 ppm in the subchronic study (NTP, 1992).

Furthermore, according to USDA (2003), two studies suggest conflicting results of glyphosate's effect on mating, fertility, and reproduction parameters (including libido level, ejaculate volume, sperm count, semen fructose level and osmolarity, and number of abnormal or dead sperm) (Yousef et al., 1996; Schroeder and Hogan, 1981. Yousef et al. (1996) found that all of the effects seen in rabbits were statistically significant; however the study does not provide the actual doses used, nor does it specify the exact formulation. The study by Schroeder and Hogan (1981) suggests no treatment-related effects of glyphosate at doses of 3, 10, or 20 mg/kg body weight, although some changes in kidney morphology were observed at 30 mg/kg/day. The basis for inconsistency lies in the reporting and experimental design limitations and deficiencies in Yousef's study. Also, the use of gelatin capsules in Yousef et al. (1995) makes the study less comparable and relevant to potential human exposure (USDA, 2003).

With regard to human health effects, several epidemiological studies have been conducted to assess the relationship between general or overall pesticide exposure, or assumed pesticide exposure, and reproductive health outcomes. However most of them have not characterized exposures to specific pesticides (Arbuckle and Sever, 1998). Of the few studies that have linked exposure to glyphosate to potential risks, no adverse reproductive effects were noted. For example, the Ontario Farm Health Study, three retrospective cohort studies (Arbuckle et al., 2001; Curtis et al., 1999; Savitz et al., 1997) collected data on the relationship between pregnancy outcomes and pesticide use among couples living on farms in Ontario. Risk of miscarriage, spontaneous abortions, and fecundity were all found to be unrelated to glyphosate formulation use and exposure (USDA, 2003).

### *3.1.10 Carcinogenicity and Mutagenicity*

EPA (1993; 2002) and WHO (1994) have reviewed information regarding the carcinogenicity and mutagenicity of glyphosate. EPA classified glyphosate as a Group E carcinogen (evidence of non-carcinogenicity for humans). In the RED, EPA (1993) concluded that glyphosate is not carcinogenic at any of the levels tested in three studies. These studies are discussed in the following paragraphs. EPA (2002) reconfirmed this decision in a subsequent tolerance publication for glyphosate.

In the first study considered in the RED, Sprague-Dawley rats were fed glyphosate at levels of 0, 3, 10 or 31 mg/kg/day in males and 0, 3, 11 or 34 mg/kg/day in females for 26 months. The high dose groups showed signs of increased incidence of thyroid C-cell carcinomas in females and interstitial cell testicular tumors, but EPA determined that these neoplasms were not treatment-related, noted that the incidence of thyroid carcinomas was not statistically significant, and determined that the incidence of testicular tumors was within historical levels. Therefore, EPA determined that glyphosate was not considered carcinogenic in this study (US EPA, 1993).

A second carcinogenicity feeding study was also conducted using Sprague-Dawley rats fed diets containing 0, 89, 362, or 940 mg/kg/day in males and 0, 113, 456, or 1183 mg/kg/day in females of glyphosate. The low- and high-dose males and females showed an increase incidence of pancreatic islet cell adenomas and hepatocellular (liver) adenomas. The mid- and high-dose animals also showed an increased incidence of thyroid C-cell adenomas. However, the pancreatic islet cell adenomas were not associated with a statistically significant positive dose-related trend, a progression to carcinomas, or dose-related increase in pancreatic hyperplasia. Additionally, a statistically significant increase in incidence of hepatocellular adenomas was not seen. The incidence was within historical range, there was no progression to carcinomas, and the incidence of hyperplasia was not compound-related. In terms of thyroid C-cell adenomas, there was no statistically significant dose-related trend in occurrence or a statistically significant increase in incidence, no progression to carcinomas, and no significant dose-related increase in hyperplasia. Therefore, glyphosate was not considered to be carcinogenic (US EPA, 1993)

Another carcinogenicity study involved an 18-month feeding study conducted with CD-1 mice using doses of glyphosate equivalent to 0, 150, 750, or 4500 mg/kg/day. The effects in the high-dose group included decreased body weight gain in both sexes, increased hepatocellular

hypertrophy, hepatocellular necrosis and interstitial nephritis in males, increased incidence of proximal tubule epithelial basophilia and hypertrophy in females, and increased incidence of renal tubular adenomas in males. Based on the effects listed above, the recommended NOAEL is 750 mg/kg/day for both sexes and the recommended LOAEL is 4500 mg/kg/day for both sexes. However, it was determined by EPA and confirmed by other experts that the adenomas occurred spontaneously and that glyphosate is not considered carcinogenic based on the results of this study (US EPA, 1993; 2006).

In a subsequent assessment, EPA (2002) addressed concerns about studies performed by Hardell and Erickson (1999a, b). The first study found that individuals in Sweden with a history of glyphosate exposure had an increased risk of developing non-Hodgkin lymphoma (Hardell and Erickson, 1999a). The second study found this risk to be statistically significant (Hardell and Erickson, 1999b). After careful review, EPA concluded that these studies did not establish a definitive link to cancer and their results were based on unverified recollection of exposure. EPA maintained its classification of glyphosate as a Group E carcinogen.

In terms of its mutagenicity, glyphosate has been shown to cause an increase in chromosomal aberration in a plant (*Allium sp.*) associated with cell abnormalities in spindle fiber (Rank et al., 1993), DNA adduct formation in mice (Reluso et al., 1998), and single strand DNA breaks in mice (Bolognesi et al., 1997). *In vitro* studies conducted by Vyse and Vigfusson (1979) and Vigfusson and Vyse (1980) indicate a significant increase in sister chromatid exchanges in human lymphocytes and conclude that glyphosate is a slight mutagen. Another positive assay was confirmed in a fruit fly study (Kale et al., 1995; Kaya et al., 2000) as well as in a study of lymphocyte cultures (Lioi et al., 1998a; Lioi et al., 1998b). Most of the remaining screening studies for mutagenicity, however, were negative.

For example, four mutagenicity studies were submitted for the reregistration of glyphosate in 1993. These studies included a gene mutation assay in an Ames Test on *Salmonella typhimurium* strains, a gene mutation assay in Chinese hamster ovary cells/hypoxanthine – guanine – phosphoribosyl transferase assay, a Structural Chromosomal Aberration Assay in male and female Sprague-Dawley rats, and a combined study employing a rec-assay using *B. subtilis* and a reverse mutation assay using *E. coli* and *Salmonella typhimurium* strains. None of these studies showed a mutagenic or clastogenic response. EPA concluded that glyphosate is not a mutagen (US EPA, 1993; 2002; USDA, 2003).

### 3.1.11 Irritation and Sensitization

According to EPA, glyphosate is classified as mildly irritating to the eyes (Category III) and slightly irritating to the skin (Category IV) based on data collected from skin and eye irritation studies during the registration process (US EPA 1993; 2006). Different formulations of glyphosate have different irritation patterns (e.g., the free acid of glyphosate is severely irritating to the eyes, but the IPA salt of glyphosate is nonirritating to the skin and eyes) (USDA, 2003). Additionally, skin sensitization tests for glyphosate were all negative (US EPA, 1993; 2006).

### 3.1.12 Systemic Toxic Effects from Dermal Exposure

Systemic toxic effects from chronic dermal exposure are less damaging than those from chronic oral exposure because glyphosate is absorbed poorly from the skin. Acute dermal exposure effects are similar to those of acute oral exposure effects (USDA, 2003). EPA classified glyphosate as a Category III for oral and dermal toxicity. The LD<sub>50</sub> value for the acute oral toxicity of glyphosate is >5,000 mg/kg (US EPA, 2006).

The EPA (1993) RED for glyphosate provides further insight into the dermal toxicity of glyphosate. The RED cites a 1982 study (MRID 00098460) with rabbits in which glyphosate was applied to intact and abraded skin at doses of 10, 1000, or 5,000 mg/kg/day, five days a week, for three weeks. The effects were minimal and included slight irritation of the abraded skin, decreased food consumption, and decreased serum lactic dehydrogenase activity at 5,000 mg/kg. In a more recent study by Pinto (1996), dermal doses of 250, 500, or 1,000 mg/kg/day caused no effects on body weight, food consumption, hematology, clinical chemistry, or organ weights. There were also no signs of irritation or pathologic changes in tissue.

#### *3.1.13 Inhalation Effects*

EPA (1993; 2006) did not require an acute inhalation study for technical grade glyphosate because of its low volatility rate. The acute inhalation LC<sub>50</sub> value of the isopropylamine salt glyphosate is >6.37 mg/L, which is equivalent to a finding of no mortality in any of the five rats of each sex exposed to this concentration for four hours (USDA, 2003). A study conducted by Jamison et al., (1986) exposed a group of human volunteers to glyphosate treated flax dust and untreated flax dust. The glyphosate treated dust consistently caused a decrease in respiratory function. It is possible that the decrease in function may have been due to a greater distribution of smaller dust particles, which are more easily inhaled, in the glyphosate treated dust.

#### *3.1.14 Toxic Relevance of Surfactants in Glyphosate Formulations*

Various formulations of glyphosate contain POEA at a level of up to approximately 20 percent (200 g/L). Tallow contains a variety of fatty acids (e.g., oleic, palmitic, stearic, myristic, and linoleic acids), as well as smaller amounts of cholesterol, arachidonic, elaidic, and vaccenic acids. While surfactants are typically classified as “inert” components in herbicides, they are not toxicologically inert. In many cases, inerts are found to be more toxic than the herbicide itself (USDA, 2003).

A study evaluating the toxicity of the POEA surfactant includes a series of teratology tests in rats using glyphosate (98.7% purity), POEA used in glyphosate formulations, and the phosphate ester neutralized POEA. Groups of pregnant female rats were dosed with glyphosate at 300, 1,000, or 3,500 mg/kg/day; POEA at 15, 100, or 300 mg/kg/day, or the neutralized POEA at 15, 50, or 150 mg/kg/day on days 6 through 19 of gestation. Results indicate that severe maternal poisoning occurred at the 3,500 mg/mg/day dose of glyphosate, in association with reduced fetal body weight and sternal ossification, as well as fetal death. At a dose of 300 mg/kg/day of POEA and 150 mg/kg/day of neutralized POEA maternal deaths were also reported. Other noteworthy results in dams were signs of mild clinical toxicity and decreased food consumption that occurred at a dose of 100 mg/kg/day POEA surfactant. No fetotoxic effects were reported at any

dose level. Based on these results, the recommended NOAELs for glyphosate, POEA, and neutralized POEA were 1000 mg/kg/day, 15 mg/kg/day, and 50 mg/kg/day, respectively (USDA, 2003).

There has been some debate regarding the acute toxicity of POEA and the determination of its LD<sub>50</sub> value compared to glyphosate. It is generally agreed that the acute toxicity of glyphosate formulations (glyphosate and surfactant; LD<sub>50</sub> in rats 5400 mg/kg/day) is almost equivalent to that of glyphosate (LD<sub>50</sub> in rats 5600 mg/kg/day) (USDA, 2003). Additionally, based on drinking water studies on both glyphosate and Roundup® (i.e., glyphosate with POEA), the surfactant does not affect the rapid elimination rate of glyphosate in mammals (NTP, 1992).

### *3.1.15 Toxic Relevance of Impurities in Glyphosate Formulations*

#### *3.1.15.1 N-nitrosoglyphosate (NNG)*

Technical grade glyphosate contains at least one impurity, N-nitrosoglyphosate (NNG). EPA determined that the NNG content in glyphosate was not toxicologically significant because more than 92% of the individual technical glyphosate samples tested contained less than 1.0 ppm NNG. There is general concern for the carcinogenic potential of nitroso compounds but it is hard to quantify (US EPA 1993; USDA, 2003).

#### *3.1.15.2 1,4-Dioxane*

1,4-Dioxane is an impurity in POEA, and EPA considers it to be a carcinogen (Class B2: Probable human carcinogen) and has derived a cancer potency factor (i.e., slope factor) of 0.011 mg/kg/day. 1,4-Dioxane is present in Roundup® at a level of approximately 0.03% (Monsanto, 1999) or 300 mg/l (330 ppm). It has been demonstrated that dioxane does not present unique toxic effects. Therefore, its toxicity (except its role as a carcinogen) is encompassed by the available toxicity data on glyphosate (USDA, 2003).

## **3.2 Exposure Assessment**

As mentioned in section 2, there are five EUPs containing glyphosate that are recommended for use on Roundup Ready® alfalfa. These products include: Roundup Original Max®, Roundup Weather Max®, and Roundup Ultra Max II® (Monsanto, 2008). Two additional products, Honcho® and Honcho Plus®, are also listed in Greenbook, an online database that partners with chemical manufacturers such as Monsanto to provide information about agricultural products (Greenbook, 2008). Each of these products contains between 41 and 48% glyphosate (Monsanto, 2004; Monsanto, 2007a; Monsanto, 2007c; Monsanto, 2007d). For purposes of this analysis, exposure estimates to the chemical glyphosate are presented as opposed to exposure estimates to the EUPs. This is because toxicological data on the EUPs, which are required to assess risk to workers, were not available at the time of the analysis.

### *3.2.1 Routes of Exposure*

Workers exposed to glyphosate in products used to treat GT alfalfa may be exposed via dermal or inhalation routes of exposure. However, EPA determined in its RED for glyphosate that the

chemical is non-volatile (US EPA, 1993). For this reason, the inhalation route of exposure is not considered in this analysis. This analysis also does not consider incidental oral exposure to glyphosate for workers. For further discussion of oral exposure for the general public, please refer to the technical report: *Health and Safety Risks from Increased Glyphosate and Other Chemical Usage on Humans (Exclusive of Field Workers)* (appendix L).

EPA's RED for glyphosate indicated that occupational exposure to glyphosate has resulted in eye and skin irritation (US EPA, 1993). Accordingly, EPA recommended that personal protective equipment be worn by mixers, loaders, and applicators of products containing glyphosate. EPA set the restricted entry level (REI) for glyphosate at 12 hours due to the potential for acute dermal toxicity and skin and eye irritation immediately after products have been applied. However, it cannot be assumed that the recommendation for personal protective equipment and the REI will be honored universally. A subsequent EPA (2006) assessment of glyphosate for use on Indian mulberry and dried peas stated that the 12 hour REI has not been implemented universally. Thus, this exposure analysis and resulting risk characterization does not assume that personal protective equipment is worn, nor does it assume that workers wait 12 hours before entering a treated field.

### 3.2.2 Application Rates

Typical single application rates of products containing glyphosate range from less than 1.5 pounds of glyphosate a.i. per acre up to 3.75 pounds of glyphosate a.i. per acre; maximum label rate for a single application on GT alfalfa is 1.55 pounds of glyphosate a.e. (Monsanto, date unknown). Application rates were determined using specific product labels for each end use product (EUP) recommended for use on GT alfalfa. Application rates on these products were presented in volume (i.e., quarts or ounces) of active ingredient per acre. These values were converted to mass (i.e., pounds) per acre by multiplying the application volume by the density of the EUP (See equations M-1 and M-2).

Equation M-1

$$Density = Mass / Volume$$

thus,

Equation M-2

$$Mass = Density * Volume$$

Density values were provided by material safety data sheets (MSDS) for each EUP. When product density was not available, the specific gravity of the EUP was used to calculate density. The specific gravity is the ratio of the product density to the density of water. It was assumed that the density of water is 1000 kg/m<sup>3</sup> (See equations M-3 and M-4).

Equation M-3

$$Specific\ gravity = Product\ density / Water\ density$$

thus,

#### Equation M-4

$$\text{Product density} = \text{Specific gravity} * \text{Water density}$$

Labels also provided application rates for the EUP as opposed to the chemical alone. Because this exposure analysis focuses on the chemical as opposed to the EUP, the percent active ingredient (i.e., glyphosate) reported by the product label was considered in the exposure equation (See equation 3). The percent of glyphosate in EUPs ranged from 41 and 48.8% (See Table M-2).

#### Equation M-5

$$\text{Application rate of glyphosate} = \text{Application rate of EUP} * \text{Percent glyphosate in EUP}$$

Application rates of the five EUP recommended for use on GT alfalfa are presented in table M-7. Please refer to appendix M-4 in this technical report for further detail on the information used to calculate application rates.

**Table M-7. Application Rates of EUPs Recommended for Use on GT Alfalfa**

| Product               | Single Use Application Rate | Reference                                         |
|-----------------------|-----------------------------|---------------------------------------------------|
| Roundup Original Max® | 1.9 lb a.i./acre            | Monsanto, 2006; Monsanto, 2007e                   |
| Roundup Weather Max®  | 1.9 lb a.i./acre            | Monsanto, 2005a; Monsanto, 2005b; Monsanto, 2007f |
| Roundup Ultra Max II® | 1.9 lb a.i./acre            | Monsanto, 2004; Monsanto 2005c; Monsanto 2003     |
| Honcho®               | 2.0 lb a.i./acre            | Monsanto, 2007a; Monsanto, 2007b                  |
| Honcho Plus®          | 2.0 lb a.i./acre            | Monsanto, 2007c; Monsanto, 2007d                  |

### 3.2.3 Occupational Exposure Scenarios

Occupational exposure to glyphosate may be categorized as general worker exposure or as accidental worker exposure. General worker exposure estimates are based on the assumption of continuous contact with a chemical. Accidental worker exposure estimates are based on specific events that may not involve exposure over extended time periods.

#### 3.2.3.1 General Worker Exposure Scenarios

In general, pesticides are applied using one of three application methods: direct foliar, broadcast foliar, and aerial. According to Monsanto, the vast majority of Roundup® brand herbicides are applied using ground equipment, which could be for either direct or foliar broadcast applications (Monsanto, date unknown). Chronic general worker exposure scenarios are described by USDA (2003) and corresponding exposure algorithms are provided in a calculations worksheet presented to USDA by SERA (2006). Regardless of the application method, general worker absorbed dermal doses ( $AD_{\text{general}}$ ) of glyphosate may be estimated by multiplying the amount of the chemical handled per day by the absorbed dose rate (See equation M-6). The amount of chemical handled per day as well as the number of acres treated in a day may vary greatly (Acquavella et al., 2006). Using SERA's (2006) algorithms, the amount of the chemical handled per day ( $Amnt$ ) is the product of the application rate and the number of acres treated per day (See equation M-7). The number of acres treated per day ( $ATD$ ) may be calculated by multiplying the number of hours spent applying the chemical by the number of acres treated per hour (SERA, 2006) (See equation M-8).

Equation M-6  

$$AD_{general} = Amnt * ADR$$

Where:

$AD_{general}$  = absorbed dermal dose (mg/kg BW/day)  
 $Amnt$  = amount of chemical handled per day (lb/day)  
 $ADR$  = absorbed dermal dose rate (mg/kg BW per lb applied)

Equation M-7  

$$Amnt = AR * ATD$$

Where:

$Amnt$  = amount of chemical handled per day (lb/day)  
 $AR$  = application rate (lb/acre)  
 $ATD$  = acres treated per day (acres/day)

Equation M-8  

$$ATD = Hrs * APH$$

Where:

$ATD$  = acres treated per day (acres/day)  
 $Hrs$  = hours of application per day (hours/day)  
 $APH$  = acres treated per hour (acres/hour)

Absorbed dose rates ( $ADR$ ) for different application scenarios were estimated by SERA (2001). These rates will be considered constants for the present analysis. Central, upper, and lower bound rate estimate for directed foliar, broadcast foliar, and aerial application methods may be found in table M-8. USDA (2003) validated these rates for direct foliar applications by analyzing urine samples of agricultural workers exposed to glyphosate. Using biomonitoring data in addition to application rates and urinary output and bodyweight defaults, exposure rates were calculated. Three worker studies were examined and the results indicated that the upper range (0.01 mg/kg body weight per pound applied) is likely to overestimate exposure as all of the rates based on biomonitoring data were much lower. Therefore, these absorbed dose rates represent conservative assumptions that will be protective of the general worker population.

**Table M-8. Absorbed Dose Rates (in mg/kg body weight per pound of active ingredient applied)**

| Exposure Scenario | Central | Lower    | Upper  | Reference  |
|-------------------|---------|----------|--------|------------|
| Directed foliar   | 0.003   | 0.0003   | 0.01   | SERA, 2001 |
| Broadcast foliar  | 0.0002  | 0.00001  | 0.0009 |            |
| Aerial            | 0.00003 | 0.000001 | 0.0001 |            |

An application rate ( $AR$ ) of 2.0 pounds a.i. per acre was used because it is the more conservative of the single use application rates for the 5 EUPs recommended for use GT alfalfa (See table M-8). This rate is consistent with the range of application rates typical of Monsanto herbicides containing glyphosate (Monsanto, date unknown). (It is unlawful to apply glyphosate to GT alfalfa at a rate higher than 1.55 pounds of glyphosate a.e.)

Default values may also be used for the hours of application per day (*Hrs*) and the number of acres treated per hour (*APH*). USDA estimated that workers may spend between 6 (lower bound) and 8 (upper bound) hours applying chemicals per day (USDA, 1989). USDA (1989) also suggested default values for the number of acres treated per hour. These values differ depending on the pesticide application method. Workers using the direct foliar application method may cover approximately 0.625 acres/hour (range: 0.25 to 1 acre/hour). Workers using the broadcast foliar method may cover approximately 16 acres/hour (range: 11 to 21 acres/hour). Workers using the aerial application method may cover approximately 70 acres/hour (range: 40 to 100 acres/hour).

Central, lower, and upper bound exposure estimates were calculated for the three different application scenarios. Results are presented in table M-9. Central estimates for the three different application exposure scenarios ranged from 2.63E-02 to 2.94E-02 mg/kg body weight per day. Upper estimates ranged from 1.60E-01 to 3.02E-01 mg/kg body weight per day.

**Table M-9. Chronic Exposure Estimates for General Worker Exposure Scenarios (in mg/kg body weight per day)**

| Exposure Scenario | Central Estimate | Lower Estimate | Upper Estimate |
|-------------------|------------------|----------------|----------------|
| Directed foliar   | 2.63E-02         | 9.00E-04       | 1.60E-01       |
| Broadcast foliar  | 4.48E-02         | 1.32E-03       | 3.02E-01       |
| Aerial            | 2.94E-02         | 4.80E-04       | 1.60E-01       |

### 3.2.3.2 Accidental Worker Exposure Scenarios

Accidental exposure scenarios may involve multiple routes of exposure, including oral and inhalation in addition to dermal exposure. However, due to a dearth of validated quantitative models to estimate oral and/or inhalation dose to workers, this analysis focuses on accidental dermal exposures only. There are many possible accidental exposure scenarios that could be considered. The scenarios included in this analysis are an accidental spill on the hands of the worker and an accidental spill on the lower legs of the worker. This analysis assumes that the worker was not wearing personal protective equipment on the hands or legs, thus the chemical contacted the skin directly. Acute scenarios for accidental worker exposure are described by USDA (2003) and corresponding exposure algorithms are provided in a calculations worksheet presented to USDA by SERA (2006).

The worker's absorbed dermal dose from a spill on the hands or lower legs ( $AD_{spill}$ ) may be estimated by dividing the product of the absorbed dermal dose from a chemical spill on the hands or legs and the proportion of the chemical absorbed by the body weight of the worker (see equation M-9). The amount of the chemical deposited on the skin ( $Amnt$ ) may be estimated by multiplying the amount of liquid that adheres to the worker's skin, the surface area of the workers hands or legs, and the concentration of the chemical in the solution (equation M-10). The proportion of the chemical absorbed over the time that the worker is exposed ( $Prop$ ) may be estimated using equation M-11.

Equation M-9

$$AD_{spill} = Amnt * Prop / BW$$

Where:

|              |   |                                                          |
|--------------|---|----------------------------------------------------------|
| $AD_{spill}$ | = | absorbed dermal dose from spill on hands or legs (mg/kg) |
| $Amnt$       | = | amount of chemical deposited on skin (mg)                |
| $Prop$       | = | proportion absorbed over exposure duration (unitless)    |
| $BW$         | = | body weight of worker (kg)                               |

#### Equation M-10

$$Amnt = L * SA * Conc$$

Where:

|           |   |                                                                          |
|-----------|---|--------------------------------------------------------------------------|
| $SkinDep$ | = | amount of chemical deposited on skin (mg)                                |
| $L$       | = | amount of liquid that adheres to the worker's skin (mL/cm <sup>2</sup> ) |
| $SA$      | = | surface area of the worker's hands or legs (cm <sup>2</sup> )            |
| $Conc$    | = | concentration of the chemical in the solution (mg/mL)                    |

#### Equation M-11

$$Props = 1 - \exp(-ka * ED)$$

Where:

|           |   |                                                       |
|-----------|---|-------------------------------------------------------|
| $PropAbs$ | = | proportion absorbed over exposure duration (unitless) |
| $ka$      | = | dermal absorption rate (per hour)                     |
| $ED$      | = | exposure duration (hours)                             |

Default values were used for some of the variables used to characterize accidental exposure to workers. The body weight ( $BW$ ) of the worker is assumed to be 71.8 kg which is the mean adult body weight recommended by the EPA's Exposure Factors Handbook (US EPA, 1997). The amount of liquid that can adhere to the skin ( $L$ ) at a given time was estimated by Mason and Johnson (1987). According to their analysis, 0.008 mL of liquid can adhere to 1 cm<sup>2</sup> of skin. Surface area ( $SA$ ) estimates of the worker's hands and lower legs are from EPA's Dermal Exposure Assessment: Principles and Applications report (1992). It is assumed that the worker's hands have a surface area of 840 cm<sup>2</sup> and that the lower legs have a surface area of 2070 cm<sup>2</sup>. The concentration of the chemical in the solution ( $Conc$ ) was found on the label of each EUP. The maximum concentration in solution is 540 mg/mL and the minimum is 365 mg/mL. Central and lower limit exposure estimates assume the minimum concentration while upper limit exposure estimates assume the maximum concentration in solution. Assumptions regarding the dermal absorption rate ( $ka$ ) are based on a study by Wester et al. (1991) on the ability of glyphosate to bind to the skin, absorb and distribute in tissue. Dermal absorption rates range from 1.3E-04 to 1.0E-03 per hour. Finally, it is assumed that a worker's skin or lower legs would be exposed for a period of one hour ( $ED$ ).

Central, lower, and upper bound exposure estimates were calculated for two accidental exposure scenarios in which the worker's hands or lower legs are exposed for one hour. Results are presented in table M-10. Central estimates for the accidental exposure scenarios ranged from 1.40E-02 to 3.45E-02 mg/kg body weight per day. Upper estimates ranged from 5.05E-02 to 1.24E-01 mg/kg body weight per day.

**Table M-10. Acute Exposure Estimates for Accidental Worker Exposure Scenarios (in mg/kg body weight per day)**

| Exposure Scenario | Central Estimate | Lower Estimate | Upper Estimate |
|-------------------|------------------|----------------|----------------|
| Spill on hands    | 1.40E-02         | 4.44E-03       | 5.05E-02       |
| Spill on legs     | 3.45E-02         | 1.09E-02       | 1.24E-01       |

### 3.2.4 Summary

#### 3.2.4.1 General Worker Exposure Scenarios

General worker exposure estimates from direct foliar application of herbicides recommended for use on GT alfalfa ranged from 9.00E-04 to 1.60E-01 mg/kg body weight per day. General worker exposure estimates from broadcast foliar application of herbicides recommended for use on GT alfalfa ranged from 1.32E-03 to 3.02E-01 mg/kg body weight per day. General worker exposure estimates from aerial application of herbicides recommended for use on GT alfalfa ranged from 4.80E-04 to 1.60E-01 mg/kg body weight per day. Section 3.4 places these exposure estimates in the context of a glyphosate-specific human health benchmark in order to estimate risk of potential adverse effects associated with chronic dermal exposure to glyphosate.

#### 3.2.4.2 Accidental Worker Exposure Scenarios

Exposure estimates from an accidental spill on a worker's hands ranged from 4.44E-03 to 5.05E-02 mg/kg body weight per day. Exposure estimates from an accidental spill on a worker's legs ranged from 1.09E-02 to 1.24E-01 mg/kg body weight per day. Section 3.4 places these exposure estimates in the context of a glyphosate-specific human health benchmark in order to estimate risk of potential adverse effects associated with acute dermal exposure to glyphosate.

## 3.3 Dose-Response Assessment

### 3.3.1 Overview

An RfD is defined as a level of exposure that will not result in any adverse effects in any individual. The oral RfD value for glyphosate proposed by EPA's Office of Pesticide Programs (EPA OPP) is 2 mg/kg/day, and is based on a teratogenicity study in rabbits in which there were no observed effects in offspring at any dose level, and maternal toxicity was noted at 350 mg/kg/day with a NOAEL of 175 mg/kg/day (Rodwell et al., 1980). The RfD of 2 mg/kg/day was derived by dividing the NOAEL by an uncertainty factor of 100 (i.e., 10 for sensitive individuals and 10 for species-to-species extrapolation) and rounding the result to one significant figure (US EPA 2006; 2002; 1993).

### 3.3.2 Existing Guidelines

This section reviews two chronic RfDs for glyphosate proposed by EPA OPP and WHO's comparable proposed acceptable daily intake (ADI) in its analysis. As discussed in the previous paragraph, the RfD of 2 mg/kg/day was derived from a teratogenicity study in rabbits and was first derived in the 1993 RED document for glyphosate (US EPA, 1993). EPA's Integrated Risk Information System (IRIS) also derived an RfD for glyphosate of 0.1 mg/kg/day (US EPA, 1990). This value is based on a dietary 3-generation reproduction study by Schroeder and Hogan

(1981), in which rats were exposed to glyphosate in their diet and no adverse effects were observed. The NOAEL from this study was 10 mg/kg/day and an uncertainty factor of 100 was applied to derive an RfD of 0.1 mg/kg/day.

The ADI proposed by WHO (1994) is based on a life-time feeding study in rats, as opposed to a reproductive toxicity study. A study by Lankas and Hogan (1981) dosed the diets of male and female rats daily with glyphosate for 26 months (0, 3.1, 10.3, or 31.5 mg/kg/day in males; 0, 3.4, 11.3, or 34.0 mg/kg/day in females). No effects were observed in any of the animals at any of the dose levels; therefore, WHO used a NOAEL of 31.5 mg/kg/day and an uncertainty factor of 100 to derive the ADI.

EPA's Office of Drinking Water (EPA ODW) proposed a 10-day health advisory for glyphosate of 17.5 mg/L, based on the NOAEL of 175 mg/kg/day, and a longer-term health advisory of 1 mg/L, based on the EPA RfD of 0.1 mg/kg/day. EPA ODW also derived a short-term RfD of 2 mg/kg/day, which is identical to the chronic RfD proposed by EPA OPP.

### *3.3.3 Dose-Response and Dose-Severity Relationships*

A threshold and non-threshold multistage model was used to estimate the LD<sub>50</sub> in humans. Both models approximated the LD<sub>50</sub> to be 3,000 mg/kg/day, similar to the range of 2,000 to 6,000 mg/kg reported in experimental mammals. The threshold version of the multistage model was also used to yield an estimate of the threshold dose of 445 mg/kg for systemic toxic effects. Below this dose, it is assumed that no individual in the population will respond (USDA, 2003).

In addition, dose severity relationships were analyzed for experimental mammals and humans. The available animal data were characterized using four standard severity levels: NOEL, NOAEL, AEL (adverse effect level), and FEL (frank effect level). Furthermore, three different groups of end points were determined: general systemic toxic effects, reproductive or developmental effects, and acute LD<sub>50</sub> values. Although the exposure periods for these studies ranged from one day to greater than two years, glyphosate was rapidly excreted from the body. Therefore, it may be assumed that duration of exposure is not a crucial parameter in assessing the toxicity of glyphosate (USDA, 2003).

The data for experimental animals was further analyzed using a categorical regression analysis in the next step of assessing the dose-severity relationships. The analysis correlates categorical responses with factors that may influence the response. Results of the categorical regression indicate that the probabilities of an adverse effect at the RfD of 0.1 mg/kg/day is 0.0005, at 1 mg/kg/day is 0.003, and at a dose of 10 mg/kg/day is 0.12. From these results, it was inferred that an RfD of 2 mg/kg is protective. It was further determined that the probability of a frank toxic effect (a sufficiently severe effect that can be observed in the whole organism without the use of invasive methods) at the RfD of 0.1 mg/kg/day is 0.00005 and at the RfD of 2 mg/kg/day increases to 0.0006 (USDA, 2003).

The consistency between the categorical analysis in experimental animals and the dose-response analysis using the multistage model for humans is relatively good. At 445 mg/kg, the estimated

threshold of human lethality, the probability of observing a frank toxic effects is approximately 0.04. At this dose in the non-threshold version of the multi-stage model, the probability is 0.02. At the estimated human LD<sub>50</sub> of approximately 3000 mg/kg, the probability of observing an adverse or frank effect, as determined by a categorical regression using two categories, is 0.7.

For glyphosate, the data suggest that humans are no more sensitive than experimental animals. Subsequently, this suggests that the current and proposed RfDs may be overly protective by a factor of 10 or greater.

#### 3.3.4 *Susceptible Populations*

In developmental studies in rats and rabbits and reproductive studies in rats, glyphosate exhibited no evidence of increased qualitative and quantitative susceptibility. Additionally, an acute RfD was not established for any population subgroup or the general population, including infants and children, based on the absence of an appropriate toxicological endpoint attributable to a single exposure (dose), including maternal toxicity in developmental toxicity studies (US EPA, 2006).

#### 3.3.5 *RfD Values Used in Risk Assessment*

The glyphosate database is large, complex, and open to many interpretations. The Joint Food and Agricultural Organization of the United Nation (FAO)/WHO on Pesticides Residues (JMPR) recommended an ADI for glyphosate of 0.3 mg/kg *per se*. This was based on a 26-month feeding study in rats with a resulting NOEL of >31 mg/kg/day and an uncertainty factor of 100. However, EPA determined a NOAEL of 175 mg/kg/day and an uncertainty factor of 100 because maternal mortality was observed at the highest dose group. As a result, in 1992, EPA OPP's Reference Dose Peer Review Committee recommended an oral reference dose for glyphosate of 2 mg/kg/day for long-term exposures (USDA, 2003). EPA ODW recommended an oral reference dose of 2 mg/kg/day for short-term exposures. As a result, the same RfD is recommended for both short- (i.e., acute) and long-term (i.e., chronic) exposures. Due to a lack of significant dose-response data for glyphosate, this approach was deemed appropriate (USDA, 2006; US EPA 1993; 2002). Glyphosate endpoints for this risk assessment are summarized in table M-11 below.

EPA did not include an RfD for dermal exposure to glyphosate (1993). However, following the lead of USDA (2003), a dermal RfD of 2 mg/kg/day was used for short- and long-term dermal exposures.

**Table M-11. Summary of Toxicological Doses and Endpoints for Chemical for Use in Human Health Risk Assessments (US EPA, 2006)**

| <b>Exposure Scenario</b>                                                                                              | <b>Dose Used in Risk Assessment, UF</b>                                                                                                                                    | <b>Special FQPA SF* and Level of Concern for Risk Assessment</b>                 | <b>Study and Toxicological Effects</b>                                                                                                                                                                                        |
|-----------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Chronic Dietary (all populations)                                                                                     | NOAEL= 175 mg/kg/day<br>UF = 100<br><b>Chronic RfD</b> = 1.75 mg/kg/day = 2.0 mg/kg/day (rounded to one significant figure)                                                | FQPA SF = 1X<br><b>cPAD</b> = $\frac{cRfD}{FQPA\ SF}$<br>= <b>1.75 mg/kg/day</b> | Developmental Toxicity Study - rabbit<br>LOAEL = 350 mg/kg/day based on diarrhea, nasal discharge and death in maternal animals                                                                                               |
| Short-, and Intermediate-Term Incidental, Oral (Residential)                                                          | NOAEL = 175 mg/kg/day                                                                                                                                                      | LOC for MOE = 100                                                                | Developmental Toxicity Study - rabbit<br>LOAEL = 350 mg/kg/day based on diarrhea, nasal discharge and death in maternal animals                                                                                               |
| Short-, Intermediate- and Long-Term Dermal (1 - 30 days, 1-6 months, 6 months -lifetime ) (Occupational)              | 2.0 mg/kg/day [US EPA does not maintain a dermal RfD; however, USDA (2003) used an acute and chronic RfD to conduct a dermal exposure assessment for occupational workers] | None                                                                             | Based on the systemic NOAEL of 1,000 mg/kg/day in the 21 day dermal toxicity study in rabbits, and the lack of concern for developmental and reproductive effects, the quantification of dermal risks is not required.        |
| Short-, Intermediate- and Long-Term Inhalation (1-30 days, 1- 6 months, 6 months-lifetime) (Occupational/Residential) | None                                                                                                                                                                       | None                                                                             | Based on the systemic toxicity NOAEL of 0.36 mg/L (HDT) in the 28-day inhalation toxicity study in rats, and the physical characteristics of the technical (wetcake), the quantification of inhalation risks is not required. |
| Cancer (oral, dermal, inhalation)                                                                                     | <b>Classification:</b> Group E; no evidence of carcinogenicity; risk assessment not required                                                                               |                                                                                  |                                                                                                                                                                                                                               |

### 3.4 Risk Characterization

#### 3.4.1 Overview

As discussed in section 3.2, workers may be exposed to herbicides recommended for used on GT alfalfa via dermal contact with treated crops. Workers may also be exposed accidentally via spills to hands or legs. Glyphosate is considered a Category IV dermal toxicant and may cause slight skin irritation (US EPA 1993; 2006).

#### 3.4.2 Risk Characterization

To determine if workers are at risk of adverse effects associated with glyphosate, estimated exposure doses are compared with a health benchmark specific to glyphosate. As discussed in section 3.3, USDA (2003) used a dermal reference dose (RfD) for acute (i.e., accidental) and chronic (i.e., general) exposure scenarios for glyphosate of 2 mg/kg of body weight per day.

This means that individuals with dermal exposure doses equal to or less than 2 mg/kg of body weight per day should not be at risk of adverse effects associated with exposure to glyphosate. The risk metric used to determine if individuals are at risk of adverse effects is called the hazard quotient (HQ). The hazard quotient is the ratio of the estimated exposure dose to the chemical-specific health benchmark (e.g., RfD) (See equation M-12). If the HQ is estimated to be less than 1, no adverse effects are expected as a result of exposure to the chemical of concern. If the HQ is greater than 1, adverse health effects are possible. However, an HQ exceeding 1 does not indicate that adverse effects are certain to occur. Since glyphosate is considered a Group E carcinogen (i.e., signifies non-carcinogenicity in humans) (EPA, 1993), an analysis of cancer risk was not conducted.

Equation M-12.

$$HQ = \frac{Exposure}{RfD}$$

Where:

HQ = Hazard quotient (unitless)  
 Exposure = Estimated exposure dose (mg/kg BW per day)  
 RfD = Reference dose (mg/kg BW per day)

#### Risk Characterization for General Worker Exposure Scenarios

Chronic dermal exposure estimates for three occupational scenarios in which a worker applies glyphosate using a directed foliar, broadcast foliar, or aerial application method were presented in section 3.2. Results are summarized in table M-12. Please refer to the calculations worksheet submitted with this report for further explanation of exposure calculations.

**Table M-12. Chronic Dermal Exposure Estimates by Method of Application (in mg/kg BW per day)**

| Scenario         | Central Estimate | Lower Estimate | Upper Estimate | Worksheet |
|------------------|------------------|----------------|----------------|-----------|
| Directed Foliar  | 2.63E-02         | 9.00E-04       | 1.60E-01       | 1         |
| Broadcast Foliar | 4.48E-02         | 1.32E-03       | 3.02E-01       | 2         |
| Aerial           | 2.94E-02         | 4.80E-04       | 1.60E-01       | 3         |

Chronic dermal exposure estimates were compared to the chronic dermal RfD of 2 mg/kg of body weight per day. Results are presented in table M-13. Please refer to the calculations worksheet submitted with this report for further explanation of hazard quotient calculations.

**Table M-13. Chronic Dermal HQs for General Worker Exposure Scenarios**

| Scenario         | Central Estimate<br>(in mg/kg BW<br>per day) | Lower Estimate<br>(in mg/kg BW<br>per day) | Upper Estimate<br>(in mg/kg BW<br>per day) | RfD<br>(in mg/kg BW<br>per day) | Worksheet |
|------------------|----------------------------------------------|--------------------------------------------|--------------------------------------------|---------------------------------|-----------|
| Directed Foliar  | 0.0131                                       | 0.0005                                     | 0.0800                                     | 2                               | 7         |
| Broadcast Foliar | 0.0224                                       | 0.0007                                     | 0.1512                                     |                                 |           |
| Aerial           | 0.0147                                       | 0.0002                                     | 0.0800                                     |                                 |           |

### 3.4.2.2 Risk Characterization for Accidental Worker Exposure Scenarios

Acute dermal exposure estimates for two spill scenarios in which a worker spills glyphosate on the hands or legs were presented in section 3.2. Results are summarized in table M-14. Please refer to the calculations worksheet submitted with this report for further explanation of exposure calculations.

**Table M-14. Acute Dermal Exposure Estimates by Type of Spill (in mg/kg BW per day)**

| Scenario       | Central Estimate | Lower Estimate | Upper Estimate | Worksheet |
|----------------|------------------|----------------|----------------|-----------|
| Spill on hands | 1.40E-02         | 4.44E-03       | 5.05E-02       | 4         |
| Spill on legs  | 3.45E-02         | 1.09E-02       | 1.24E-01       | 5         |

Acute exposure estimates were compared to the acute dermal RfD of 2 mg/kg of body weight per day. Results are presented in table M-15. Please refer to the calculations worksheet submitted with this report for further explanation of hazard quotient calculations.

**Table M-15. Acute Dermal HQs for General Worker Exposure Scenarios**

| Scenario       | Central Estimate<br>(in mg/kg BW<br>per day) | Lower Estimate<br>(in mg/kg BW<br>per day) | Upper Estimate<br>(in mg/kg BW<br>per day) | RfD<br>(in mg/kg BW<br>per day) | Worksheet |
|----------------|----------------------------------------------|--------------------------------------------|--------------------------------------------|---------------------------------|-----------|
| Spill on hands | 0.007                                        | 0.002                                      | 0.025                                      | 2                               | 7         |
| Spill on legs  | 0.017                                        | 0.005                                      | 0.062                                      |                                 |           |

### 3.4.3 Summary of Results

This analysis assumes that workers exposed to glyphosate may have chronic or acute dermal exposure. The scientific literature demonstrates that general worker exposure estimates vary greatly because the amount of chemical handled per day and the number of acres treated in a day differs from scenario to scenario. Central, lower, and upper bound exposure and risk calculations are intended to capture some of this variability.

#### 3.4.3.1 Chronic Dermal Risk Characterization

Central, lower, and upper bound HQs for general worker exposure scenarios do not suggest that workers are at risk of adverse effects associated with chronic dermal exposure to glyphosate. HQs ranged from 0 to 0.8 for directed foliar application, from 0.001 to 0.15 for broadcast foliar application and from 0 to 0.08 for aerial application. The most exposed workers were those using a broadcast foliar application method. The upper bound HQ was 0.15, approximately 8% of the chronic dermal RfD.

#### 3.4.3.2 Acute Dermal Risk Characterization

Central, lower, and upper bound HQs for acute worker exposure scenarios do not suggest that workers are at risk of adverse effects associated with acute dermal exposure to glyphosate. HQs for a spill on the hands ranged from 0.002 to 0.025. HQs for a spill on the legs ranged from

0.005 to 0.062. The most exposed workers were those who spilled glyphosate on the legs. The upper bound HQ was 0.06, approximately 3% of the acute dermal RfD.

### 3.5 Summary of Findings

The use of currently registered pesticide products containing glyphosate in accordance with the labeling will not pose unreasonable risks or adverse effects to humans or the environment. In general, the herbicidal activity of glyphosate is due primarily to a metabolic pathway that does not occur in humans or other animals, and, thus, this mechanism of action is not directly relevant to the human health risk assessment. EPA considers glyphosate to be of low acute and chronic toxicity by the dermal route of exposure. Glyphosate is considered a Category IV dermal toxicant and is expected to cause only slight skin irritation.

General or chronic worker exposure estimates from directed foliar application of herbicides recommended for use on GT alfalfa ranged from 9.00E-04 mg/kg/day to 1.60E-01 mg/kg/day. Chronic exposure estimates from broadcast foliar application ranged from 1.32 E-03 to 3.02E-01 mg/kg/day. Chronic exposure estimates from aerial application ranged from 4.80E-04 to 1.60E-01 mg/kg/day.

Central, upper, and lower bound chronic HQs were all under 1, suggesting that workers using these methods of application to apply herbicides recommended for use on GT alfalfa are not at risk of adverse effects associated with dermal exposure to glyphosate. HQs for directed foliar application ranged from 0 to 0.8. HQs for broadcast foliar application ranged from 0.001 to 0.15. HQs for aerial application ranged from 0 to 0.08. The most exposed workers were those using a broadcast foliar application method. The upper bound HQ was 0.15, approximately 8% of the chronic dermal RfD.

Accidental or acute worker exposure estimates from an accidental spill of herbicides recommended for use on GT alfalfa on the hands ranged from 4.44E-03 mg/kg/day to 5.05E-02 mg/kg/day. Acute worker exposure estimates from an accidental spill on the legs ranged from 1.09E-02 mg/kg/day to 1.24E-01 mg/kg/day.

Central, upper, and lower bound HQs were all under 1, suggesting that workers who accidentally spill herbicides recommended for use on GT alfalfa on hands or legs are not at risk of adverse effects associated with acute exposure to glyphosate. HQs for a spill on the hands ranged from 0.002 to 0.025. HQs for a spill on the legs ranged from 0.005 to 0.062. The most exposed workers were those who spilled glyphosate on the legs. The upper bound HQ was 0.06, approximately 3% of the acute dermal RfD.

## Appendix M-2. Literature Search

### 1.0 Literature Search Strategy

#### 1.1 Purpose

The purpose of this literature search is to locate references about the health and safety risks for field workers from increased glyphosate usage. These references will be used to examine the literature on potential health and safety risks for field workers.

We propose that the following DIALOG databases be included in the search:

The following DIALOG databases will be included in the search:

|                                    |                                                 |
|------------------------------------|-------------------------------------------------|
| File 5: BIOSIS                     | File 117: Water Resources Abstracts             |
| File 6: NTIS                       | File 144: PASCAL                                |
| File 34: SciSearch                 | File 154: MEDLINE                               |
| File 41: Pollution Abstracts       | File 156: ToxFile                               |
| File 40: Enviroline                | File 245: WATERNET™                             |
| File 72: EMBASE                    | File 250: CAB Abstracts                         |
| File 76: Environmental Sciences    | File 266: Federal Research In Progress (FEDRIP) |
| File 79: Aqualine                  | File 399: CA SEARCH®: Chemical Abstracts®       |
| File 98: General Science Abstracts |                                                 |

Descriptions of these files are available at <http://library.dialog.com/bluesheets/>.

#### 1.2 Scope of Search

The search will focus any published references after 1990. A reference list with abstracts will be screened for relevance to fermentation processes. English language only publications will be retrieved.

The following list will be retrieved and expanded upon.

#### 1.3 Strategy Overview

A list of search parameters is listed below.

#### 1.4 Synonyms

- Glyphosate
- Glyphosate, isopropylamine salt
- Glyphosate, sodium salt
- *N*-(phosphonomethyl) glycine
- Roundup®
- Rodeo®

- Glyphosate, potassium
- Glyphosate, ammonium
- Glyphosate, sulfosate
- Aqua Star
- Shackle®
- Roundup Ultra®

## 1.5 Keywords

- Acute
- Alfalfa
- Allowable daily intake
- Cancer\*
- Carcino\*
- Chronic
- Crop
- Degradation
- Derma\*
- Developmental
- Dietary risk
- Dose
- Emission
- Embryo
- Environmental impacts
- Exposure(s)
- Eye
- Farm
- Farmworker
- Fertility
- Fieldworker
- Health effect(s)
- Human health risk
- Incidental
- Ingest\*
- Inhal\*
- Inhibition
- Irritation
- Leach\*
- Metabo\*
- Mutagen\*
- Neuro\*
- Non-target crops
- Occupational
- Persistence
- Reproducti\*
- Residue
- Risk
- Sensitization
- Spray drift
- Subchronic
- Terato\*
- Tolerance
- Toxic\*
- Usage patterns
- Worker

## 1.6 Submission of Citations for Approval

Using reference management software, pooled information obtained from the various bibliographic databases will be screened to remove duplicates. Additionally, ICF will review the list prior to submission and eliminate any irrelevant citations. Information will include the following (when available):

Author(s). Publication Year. Title. Source Document Name, Volume, Page Numbers.

Abstract

Descriptors/Identifiers (*i.e.*, keywords and subject headings)

Amphibians, Plants, and Ecosystems  
from Increased Glyphosate and Other  
Chemical Usage**

# Potential Impacts to Wildlife, Amphibians, Plants, and Ecosystems from Increased Glyphosate and Other Chemical Usage

## Executive Summary

### Increased Glyphosate and Other Herbicide Use on Glyphosate-Tolerant Crops

The adoption of GT (GT) crops has caused a shift in herbicide usage; generally glyphosate usage has increased while other herbicides have declined resulting in a reduction in total herbicide usage. Several reviews concerning genetically engineered crops and herbicide use have supported this conclusion (Brimner et al., 2005; Fernandez-Cornejo, 2006; Gianessi and Reigner, 2006; Kleter et. al., 2007; Sankula, 2006; Johnson et al., 2008). However, in 2004, Charles M. Benbrook asserted that herbicide usage increased based due to the adoption of herbicide-resistant crops. The data set used to determine these trends in herbicide usage were from USDA's National Agricultural Statistics Service (NASS), which is not comprehensive and the data differs yearly as to what is reported. For example, different states report glyphosate from year to year for instance corn or soybeans. This discrepancy in reporting and data collection causes controversy over the exact amount of national use of herbicides. However, all analyses agreed that the herbicide glyphosate usage increased due to the adoption of GT crop technologies. This technical report will focus mainly on the environmental risk of glyphosate in comparison to herbicides commonly used on conventional alfalfa. GT alfalfa is cultivated almost identically to conventional alfalfa except for the use of glyphosate during post emergence.

### Herbicides Associated With Alfalfa Farming

Herbicides related to alfalfa farming can be divided into two major groups. One group includes herbicides that do not kill alfalfa (e.g., 2,4-DB, benefin, bromonoxynil, clethodim, diuron, S-ethyl dipropyl(thiocarbamate) (EPTC), hexazinone, imazamox, imazethapyr, metribuzin, norfluzon, paraquat, pronamide, sethoxydim, terbacil, and trifluralin), and are, therefore, used to control weeds in alfalfa. The other group includes herbicides that kill alfalfa (e.g., 2,4-D, dicamba, clopyralid, and picloram), so they are used for stand removal. Adoption of GT alfalfa decreases the number of herbicides used to control weeds in alfalfa because glyphosate is a preferred broad spectrum herbicide for GT alfalfa.

On the other hand, relying on glyphosate alone as the only weed removal herbicide may increase glyphosate-resistant weeds; for more information on this subject, refer to the technical reports *Effects of Glyphosate-Resistant Weeds in Agricultural Systems* (appendix G) and *Effects of Glyphosate-Resistant Weeds in Non-Agricultural Ecosystems* (appendix H). With an increase in glyphosate resistant weeds due to the adoption of GT alfalfa, there may be a corresponding increase in the use of other herbicides used for stand removal. Overall, however, herbicide shifts due to stand removal would be smaller in magnitude than herbicide shifts due to weed control.

## Glyphosate Usage and Chemical Fate in the Environment

Glyphosate is a broad spectrum herbicide. It is a systemic, post-emergence herbicide widely used on agricultural commodities (food uses) and non-agriculture sites. Glyphosate's environmental fate data is considered complete. Glyphosate absorbs directly through plant leaves and rapidly spreads throughout the plant. The use of surfactants enables greater leaf penetration. Glyphosate's mode of action is as a potent and specific inhibitor of the enzyme, 5-enolpyruvylshikimate 3-phosphate synthase (EPSPS). This enzyme is located in the shikimate pathway and is essential for the biosynthesis of aromatic amino acids and other aromatic compounds in algae, higher plants, bacteria, fungi, and apicomplexan parasites. The shikimate pathway is absent in mammals.

Glyphosate adsorbs strongly to soil and is not expected to move vertically below the six inch soil layer; residues are expected to be immobile in soil (US EPA, 1993, 2006a). Glyphosate is primarily degraded by soil microbes in the environment. The major degradate of this process is aminomethyl phosphonic acid (AMPA), which further degrades in the soil to carbon dioxide. The half-life of glyphosate in soil laboratory studies is two days (US EPA, 1993, 2006a). In agricultural soils, the disappearance time for 50% of the pesticides (DT50) of glyphosate ranges from 1.7 to 197.3 days, but is typically less than 60 days depending upon edaphic and climatic conditions (Giesy et al., 2000). Due to glyphosate and AMPA's strong adsorptive characteristics, they are not likely to leach to groundwater from the soil; however, monitoring data by USGS demonstrates low amounts of glyphosate and AMPA in groundwater, especially in heavy agricultural areas. Further discussions of environmental concentrations of glyphosate are presented below. On the other hand, glyphosate and its metabolite adsorb to soil particles that become suspended in runoff water and can potentially contaminate surface waters as a result of erosion of this soil. Once in surface water, glyphosate and AMPA are not readily broken down by water or sunlight. Bacteria and other environmental microorganisms break down both chemicals rapidly and completely (US EPA, 1993, 2006a).

## Glyphosate Occurrence in the Environment

In a USGS monitoring study of surface water, groundwater, and soil conducted from 2001 to 2006, the metabolite AMPA was observed more frequently than the parent compound glyphosate (Scribner et al., 2007). The sample collections were from several USGS studies including: the National Stream Quality Accounting Network Program, the National Water-Quality Assessment Program, and the Toxic Substances Hydrology Program. Additionally, glyphosate and its metabolite AMPA were found in surface water more frequently than groundwater. Furthermore, higher occurrences of glyphosate and AMPA in ground and surface waters were observed when samples were taken from an area with greater proximity to agricultural land with recent applications of glyphosate and a recent rain event. Glyphosate was found in rain water; however, this was due to glyphosate's association with particulate matter (dust) and not to its existence as vapor. Soil samples indicate "trace levels" glyphosate and AMPA may persist from year to year (Scribner et al., 2007); however, this is in contradiction to environmental fate and transformation data. For an in depth discussion of soil, water, and air environmental levels of

glyphosate, refer to the technical report *Effects of Changes in Farming Practices on Water, Soil and Air Due to Use of Glyphosate-Tolerant Alfalfa* (appendix J).

## Glyphosate Residue on Crops and Livestock

Studies with a variety of plants indicate that uptake of glyphosate or AMPA from soil is limited (US EPA, 2006c). For the most part, the ratio of glyphosate to AMPA is 9 to 1 but can approach 1 to 1 in some cases (e.g., soybeans and carrots). Much of the residue data for crops reflects a detectable residue of parent glyphosate (0.05 - 0.15 ppm) along with residues below the level of detection (<0.05 ppm) of AMPA (US EPA, 2006c). EPA determined that, based on toxicological considerations, AMPA need not be regulated and should be dropped from the tolerance expression (US EPA, 2006c). Metabolism studies submitted for genetically engineered GT canola and GT corn have indicated that metabolism in GT plants is essentially the same as that in normal plants (US EPA, 2006c). During a confined crop rotational study, the residues of glyphosate were undetected 30 days after treatment (US EPA, 2006c). Glyphosate is used on a large variety of crops, but only a limited number of uses generate residues in the edible parts of the crops; per Monsanto, GT alfalfa is not to be grown for human food (e.g., alfalfa sprouts). Further analysis of the human health dietary risks are discussed in the technical report, *Health and Safety Risks from Increased Glyphosate and Other Chemical Usage on Humans (Exclusive Of Field Workers)* (appendix L).

GT alfalfa is to be used as forage to many livestock. Studies with lactating goats, laying hens, rats, rabbits, and cows fed a mixture of glyphosate and AMPA indicate that the primary route of elimination is by excretion (urine and feces). The residues in eggs, milk, and livestock tissues consist of glyphosate and its metabolite, AMPA; there was no evidence of further metabolism of glyphosate or AMPA in these animals (US EPA, 2006c). Additionally the studies show that there is very little transfer of residues from feed to animal tissues and no bioaccumulation of residues occurs (US EPA, 2006c).

## Glyphosate Herbicide Usage on GT Alfalfa

Glyphosate is among the most widely used pesticides by volume in the United States and other glyphosate products are available; however, use data for GT alfalfa were only found for Monsanto products. The only products approved and that have a subsequent proposed maximum use rate for GT alfalfa are the following Monsanto glyphosate herbicide products: Honcho, Honcho Plus, Roundup Original MAX, Roundup WeatherMAX, and Roundup Ultra MAX II. Glyphosate products can be formulated to have different concentrations of glyphosate acid per gallon of product. To improve handling, performance, and concentration, the glyphosate acid is formulated as a salt compound. The term acid equivalent (a.e.) refers to the weight of the glyphosate acid, which is herbicidally active, while the term active ingredient (a.i.) is the weight of the glyphosate acid plus the salt. For the quantitative ecological Tier 1 risk assessment, the maximum use rate of 7.98 lbs a.e./acre year, with a single maximum use rate of 1.99 lb a.e./acre and a minimum reapplication rate of 7 days was used. The maximum single use rate for glyphosate on GT alfalfa is 1.55 lb a.e./acre.

## Modeled Glyphosate Residues

Exposure to aquatic species was estimated using GENEEC Version 2.1 as the Tier I simulation model. The peak concentration of glyphosate in a pond receiving runoff from a drainage basin treated 100% with glyphosate would be 15.66 µg/L (ppb) for Honcho® assuming the highest application rate. This does not exceed any Level of Concern (LOC), and longer term exposures would be lower; therefore risk is presumed to be below thresholds of concern.

Exposure to terrestrial species was estimated using Tier 1 TREX (Terrestrial Residue EXposure) simulation model (version 1.2.3) based on the maximum proposed application rate, re-application interval, and the default foliar dissipation half-life of 35 days at a rate of 1.99 lb ai/acre, applied 4 times at 30 day intervals. Residues on various terrestrial food items ranged from 61 to 968 mg/kg diet.

**Table N-1. Dietary-based Estimated Environmental Concentrations (EECs)s Upper Bound Kenaga Values from TREX model**

| <b>Food source</b>              | <b>Estimate concentration glyphosate (ppm)</b> |
|---------------------------------|------------------------------------------------|
| Short Grass                     | 968.42                                         |
| Tall Grass                      | 443.86                                         |
| Broadleaf plants/Small Insects  | 544.74                                         |
| Fruits/pods/seeds/Large insects | 60.53                                          |

These peak Estimated Environmental Concentrations (EECs) resulted in no LOC exceedences, except for the birds whose diet consists of broad leaf plants and small insects. This exceedence, however, was minor with a Risk Quotient (RQ) of 0.12; this value is slightly greater than the LOC (>0.1) for Acute Endangered Species: Endangered species may be adversely affected by use. It should be noted the EECs estimated above are based on worst case/high-end use scenario. The difference is minor and considered a minimal risk.

## Glyphosate Toxicity and Risk to the Environment

The US EPA's toxicological and ecotoxicology and fate databases on glyphosate are considered adequate and complete (US EPA, 1993; 2006a), and based on this data, glyphosate is considered to be a toxicologically and ecologically low-risk herbicide (Cerdeira and Duke, 2006). Based on the data available on glyphosate usage on GT alfalfa, chemical fate, and toxicity, and after a Tier 1 “high-end use case” scenario screening of hazard quotients, glyphosate is not expected to pose a risk to the following categories of wildlife:

- acute or chronic risk to birds
- acute or chronic risk to mammals
- acute or chronic risk to terrestrial invertebrates
- acute or chronic risk to aquatic invertebrates
- acute or chronic risk to fish

However, the use of glyphosate on GT alfalfa is expected to pose a possible risk to terrestrial and aquatic plants. Most plant species, when exposed to glyphosate, experience high levels of toxicity. Higher plants that use the shikimate pathway to produce aromatic amino acids will

experience toxic effects as they metabolize glyphosate. These toxic effects could include the inability to photosynthesize, the inability to complete respiration, and the inability to synthesize nucleic acids. Although the effects can be slow to progress, all of these toxic effects could result in plant death. Spray drift is one of the pathways of concern for non-target plants; however, if aerial applications are minimized the risk to non-target plants should be reduced. Standard toxicity studies as well as drift studies are available for several species of non-target terrestrial plants (USDA, 2003) and are presented below. AMPA, the primary degradation product of glyphosate, seems to be equally or less toxic than glyphosate; therefore, a separate risk characterization was not evaluated.

### Glyphosate Bird Toxicity

Glyphosate is practically non-toxic to birds and was not found to cause reproductive effects. Toxicity in birds was assessed using single-dose, dietary, and reproductive toxicity studies. Glyphosate acute toxicity in the Bobwhite quail was slightly toxic with the dose required to kill 50 percent of a population of test animals ( $LD_{50}$ )  $\geq 2,000$  milligrams per kilogram (mg/kg) (US EPA, 1993) or the concentration required to kill 50 percent of the test population ( $LC_{50}$ )  $> 3851$  mg a.e./kg tested as an acid (Giesy et al., 2000). Dietary studies (8-day feeding) in the Bobwhite quail and Mallard duck are considered slightly toxic for both birds  $> 4640$  mg/kg (US EPA, 1993, 2006a) and  $LC_{50} > 4640$  mg a.e./kg tested as an acid (Giesy et al., 2000). Reproductive studies did not indicate any effect after glyphosate treatment in Mallard duck or Bobwhite quail. The no observed effect concentration (NOEC) for both the mallard and Bobwhite quail was 1000 mg a.e./kg diet (US EPA, 1993, 2006a). Glyphosate tested as acid produced similar results in the Bobwhite quail and Mallard duck; studies with glyphosate tested as its isopropylamine (IPA) salt were not reported for review.

### Glyphosate Mammal Toxicity

Wild mammal toxicity testing is not required by US EPA for ecological risk assessments. In most cases, the rodent and rabbit toxicity values obtained from studies conducted to support human health risk assessments substitute for wild mammal testing. All of the acute toxicity (2,000 to 6,000 mg/kg and acute oral intraperitoneal) studies in rodents for glyphosate are slightly toxic to practically non-toxic, and a non-sensitizer. In terms of subchronic and chronic toxicity in rodents, one of the more consistent effects of exposure to glyphosate is loss of body weight. Glyphosate is a Group E carcinogen, which represents no evidence of carcinogenicity. Additionally, glyphosate is not a mutagen. Glyphosate was not found to cause reproductive or developmental effects. Glyphosate produced an acute oral  $LD_{50}$  of 5,700 mg a.e./kg/day in the goat (Giesy et al., 2000), with the product Roundup® having a  $LD_{50}$  of 4,860 mg of Roundup® product/kg/day. A robust summary of mammalian toxicity of glyphosate is provided in another technical report for this EIS entitled, *Health and Safety Risks from Increased Glyphosate and Other Chemical Usage on Humans (Exclusive of Field Workers)* (appendix M).

### Glyphosate Terrestrial Invertebrate Toxicity

Honeybees are the preferred species to assess non-target arthropod toxicity by US EPA. The LD<sub>50</sub> for glyphosate is >100 µg/honeybee (US EPA, 1993, 2006a), which is considered Practically Non-Toxic according to US EPA standards. Furthermore, formulations of glyphosate that are approved for use on GT alfalfa have LD<sub>50</sub>s that range from >100 to >326 µg/honeybee, which is also considered Practically Non-Toxic by US EPA standards (Giesy et al., 2000; Monsanto, 2005, 2006, 2007b, 2007d).

### Glyphosate Terrestrial Plant Toxicity

Glyphosate is toxic to plants. The NOEC for seed germination in both monocots and dicots is 4.5 lbs a.e./acre application rate (USDA, 2003). The highest reported NOEC for growth is 0.56 lb a.e./acre (USDA, 2003). Therefore, glyphosate is much less toxic to germinating plants than it is to the foliage of growing plants. In a vegetative vigor study (US EPA, 2006a), the most sensitive dicot was oilseed rape, displaying phototoxicity when exposed >0.038 lb a.i./A; the most sensitive monocot was winter wheat where dry weight was effects >0.049 lb a.i./A. Glyphosate was tested on 26 aquatic plant species for acute toxicity; EC<sub>50</sub> values (the concentration of a compound that produces an effect in 50 percent of the population) for glyphosate in algae are as low as 0.85 mg/L and as high as 590 mg/L (USDA, 2003). In chronic tests, the EC<sub>50</sub> for glyphosate ranged from 1.6 to 25.5 milligrams per liter (mg/L) (USDA, 2003).

### Glyphosate Soil Invertebrates and Microorganism Toxicity

Acute toxicity tests were not conducted on invertebrates and microorganisms since the life-cycles for these organisms are short. Soil microbes readily metabolize glyphosate into AMPA and other metabolites (USDA, 2003). Microorganisms produce aromatic amino acids through the shikimate pathway, similar to plants. Since glyphosate inhibits this pathway, it could be expected that glyphosate would be toxic to microorganisms. However, field studies show that glyphosate has little effect on soil microorganisms, and, in some cases, field studies have shown an increase in microbial activity (USDA, 2003).

Earthworm toxicity was evaluated over 14 days for glyphosate and for formulations of glyphosate that are approved for use on GT alfalfa. Glyphosate had a no mortality level of 3750 mg/kg soil and a NOEC of 118.7 mg kg/soil; the formulated products had LD<sub>50</sub>s ranging from > 5000 to > 10000 mg/kg dry soil (Giesy et al., 2000; Monsanto, 2005, 2006, 2007b, 2007d).

### Glyphosate Amphibian Toxicity

Glyphosate is slightly toxic to amphibians; however, some formulations of glyphosate with the surfactant polyethoxylated tallowamine POEA are very toxic to amphibians. Acute tadpole toxicity to glyphosate, measured as an LD<sub>50</sub>, ranged from > 343 to 466 mg a.e./L for the IPA salt and 78 to 180 mg a.e./L for the acid. Formulated products were more toxic in the acute tadpole tests (LC<sub>50</sub> = 8.1 to 175 mg product/L). POEA is a non-ionic surfactant used in many herbicide formulations to increase the ability of active ingredients to penetrate leaf cuticles. POEA has been found to be more toxic to amphibians and other aquatic animals than the herbicide itself (Lajmanovich, 2003). One study suggested that Roundup (in combination with POEA) could

cause high rates of mortality to amphibians (Relyea, 2005); however, the testing methods of this study have been called into question over the exposure doses exceeding application rates of glyphosate. A recent effects determination by EPA on the effect of glyphosate use on the California Red Legged Frog found no toxic effects at the maximum single application rate for glyphosate products labeled for GT alfalfa (1.55 lb/A a.e.)(<http://www.epa.gov/espp/litstatus/effects/redleg-frog/index.html#glyphosate> ).

### Glyphosate Aquatic Invertebrate Toxicity

As in amphibians and some salmonid fish, glyphosate is slightly toxic but formulations with certain surfactants are very toxic to aquatic invertebrates. Several acute and lifecycle toxicity tests have been performed and a variety of fresh water aquatic invertebrates on glyphosate and various herbicide formulations. The most sensitive species to glyphosate was *Chironomus plumosus* with a 48-hour LC<sub>50</sub> of 55 ppm (US EPA, 1993, 2006a), which is considered slightly toxic by EPA classification system. The 48-hour LC<sub>50</sub> for *Daphnia magna* ranged from 780 mg/L (tested as acid) (US EPA, 1993, 2006a) to 930 mg/L (tested as IPA salt), with a NOEC value of 560 mg/L (Giesy et al., 2000), which is considered Practically Non-Toxic according to US EPA standards. The most sensitive species to glyphosate herbicide end-use formulations was *Daphnia magna* with a 48-hour EC<sub>50</sub> of 3.0 mg/L (USDA, 2003) with orders of magnitude difference in toxicity from technical glyphosate as well. The 48-hour EC<sub>50</sub> for *Daphnia magna* ranged from 3.0 mg/L to 160 mg/L (USDA, 2003; Monsanto, 2005, 2006, 2007b, 2007d). A Maximum Allowable Toxicant Concentration (MATC) between 50 and 96 mg/L was observed for *Daphnia magna* in a flow-through study with glyphosate (US EPA, 1993, 2006a). Additionally, a flow-through study reported a 21-day NOEC of 100 mg/L (Giesey, et al., 2000), and a 21-day study identified a NOEC of 3.2 mg/L for *Daphnia magna* (Giesey, et al., 2000). In accordance with acute toxicity observations, formulations of glyphosate were more toxic to *Daphnia magna* as compared to technical glyphosate. Toxicity values (96-hour EC<sub>50</sub> or LC<sub>50</sub>) for *Gammarus pseudolimnaeus* ranged from 42 mg/L to 200 mg/L, with a NOEC value of 4.4 mg/L (Giesy et al., 2000).

### Glyphosate Fish Toxicity

A large number of studies have been performed in a variety of species of freshwater fish to determine the acute toxicity of glyphosate and glyphosate formulations approved for use on GT alfalfa. The most sensitive species to glyphosate is rainbow trout (fry), with a 96-hour LC<sub>50</sub> of 7.9 parts per million (ppm) (USDA, 2003). The 96-hour LC<sub>50</sub> for glyphosate exposure to rainbow trout ranges from 7.9 mg/L to 25,657 mg/L (USDA, 2003). This large range is most likely indicative of varying study conditions. Sockeye salmon was observed to have an 96-hour LC<sub>50</sub> ranging from 8.1 mg/L (fingerling) to 8.7 mg/L (fry), and Coho salmon was observed to have an 96-hour LC<sub>50</sub> ranging from 12.8 mg/L (fry) to 36 mg/L (glyphosate tested as acid) (USDA, 2003). Fathead minnow underwent a full life-cycle toxicity study, and the MATC was >25.7 mg/L glyphosate (US EPA, 1993). A 21-day chronic study in rainbow trout identified a NOEC of 52 mg/L (Giesy et al., 2000), whereas a study with Roundup identified a NOEC of 2.4 mg/L for rainbow trout.

Many studies have also been performed in a variety of species of freshwater fish to determine the acute toxicity of glyphosate formulations. The most sensitive species to the formulations considered was rainbow trout with a 96-hour LC<sub>50</sub> of 3.13 mg/L when treated with formulations similar to Roundup UltraMAX II and Roundup WeatherMAX (Monsanto, 2004, 2005). The 96-hour LC<sub>50</sub> for rainbow trout treated with glyphosate formulations ranged from 3.13 mg/L to 52 mg/L (Giesy et al., 2000; Monsanto, 2005, 2006, 2007b, 2007d). Sockeye salmon was observed to have a 96-hour LC<sub>50</sub> of 26.7 mg/L, and Coho salmon was observed to have a 96-hour LC<sub>50</sub> ranging from 13 ppm mg/L to 42 mg/L (Giesy et al., 2000).

### Glyphosate Marine Organism Toxicity

The saltwater and marine species tested for toxicity to glyphosate and glyphosate herbicide formulations for GT alfalfa were invertebrates. The most sensitive marine species to glyphosate was *Acartia tonsa* with a 48-hour LC<sub>50</sub> of 35.3 mg a.e./L or 49.3 mg a.e. as an IPA salt (Tsui and Chu, 2003). Additionally, a 48-hour LC<sub>50</sub> of 1.77 mg/L was determined for *Acartia tonsa* treated with the glyphosate formulation, Roundup®. Grass shrimp were reported to have a 96-hour LC<sub>50</sub> of 281 ppm (US EPA, 1993). The 48-hour level that produced toxic effects in 50 percent of the population (TL<sub>50</sub>) for Atlantic Oyster was determined to be > 10 mg/L (US EPA, 1993). The 48-hour TL<sub>50</sub> for Fiddler crab was determined to be 935 ppm (EPA, 1993).

### Other Herbicides Used on GT Alfalfa Chemical Fate in the Environment

This report was not an exhaustive examination of the chemical fate of the 20 pesticides used on GT alfalfa. Each pesticide's EPA Reregistration Eligibility Decision and MSDS were used as sources. The twenty other pesticides used on alfalfa have varying chemical fates. In general, most of these pesticides were more persistent and had higher mobility in soils, making them more apt to continually contaminate surrounding water systems. Few were even considered compounds that could bioaccumulate (e.g., clopyralid, EPTC, norflurazon, sethoxydim, and trifluralin).

### Environmental Impact of GT Alfalfa Herbicides Compared to Glyphosate

The most sensitive toxicity endpoints that were publicly available for all ecological receptors were used for the Environmental Impact Quotient (EIQ) assessment (Kovach et al., 1992 & updated annually). According to this assessment, all of the common alfalfa herbicides pose a higher risk to the environment than glyphosate, excluding EPTC. Thus with the possible replacement or decreased reliance on these pesticides with glyphosate on GT alfalfa the environmental risk is decreased. It is clear glyphosate usage trends are increasing and that it is more toxicologically and environmentally benign than the herbicides it may be replacing.

## 1.0 Introduction

### 1.1 Glyphosate-Tolerant Alfalfa Background

Alfalfa is one of the most important forage crops in the U.S. Farmers use alfalfa to feed their livestock, especially dairy cows. They grow more than 20 million acres of alfalfa across the U.S. Alfalfa is an important animal feed because of its high protein and low fiber content. Alfalfa ranks fourth on the list of most widely grown crops, behind corn, soybeans, and wheat, and it is the third most valuable crop to agriculture. Because it is widespread and typically grown as a perennial crop, alfalfa also serves as important habitat for wildlife (Hubbard, 2008).

Due to its importance, scientists have modified the genome of alfalfa to make it resistant to a herbicide. The Monsanto Company incorporated the gene sequence from a native soil microorganism, *Agrobacterium*, into the alfalfa genome to make alfalfa resistant to glyphosate, meaning it is able to survive applications of glyphosate. Glyphosate is the active ingredient in Roundup<sup>®</sup>, an herbicide produced by Monsanto. In June 2005, the U.S. Department of Agriculture approved the use of Roundup Ready<sup>®</sup> alfalfa. This glyphosate-tolerant (GT) alfalfa is the only commercially available genetically engineered alfalfa on the market. Monsanto produced GT alfalfa in partnership with the largest alfalfa seed company, Forage Genetics International. The transgene responsible for glyphosate tolerance was first introduced in soybeans in 1996, and has been commercialized in several other crops (e.g., corn, canola, and cotton). Alfalfa is the first perennial GT crop that was approved for commercial planting in the United States.

GT alfalfa will probably be used most by dairy farmers, because they often depend on pure alfalfa stands free of weeds and grasses, whereas beef cattle producers and horse owners typically feed their animals an alfalfa-grass mixed hay (Putnam, 2005). The majority of alfalfa acreage in the U.S. is planted to pure stands (40 percent), whereas a quarter is planted with grasses or another companion crop (Monsanto and Forage Genetics International, 2004).

### 1.2 Glyphosate and Other Herbicides Related to GT Alfalfa Cultivation

As mentioned above, glyphosate was first introduced as an herbicide under the trade name of Roundup by Monsanto in 1974. Before the introduction of GT crops, glyphosate was used in non-crop situations, before planting the crop, or with particular application equipment to avoid contact with the crop due to its toxicity to plants (Duke, 1988; Duke et al., 2003; Franz et al., 1997). Glyphosate is a systemic, post-emergence herbicide widely used on agricultural commodities (food uses) and non-agriculture sites. It is a very effective non-selective herbicide (Cerdeira and Duke, 2006). Glyphosate acts on various enzyme systems and inhibits amino acid metabolism in what is known as the shikimate acid pathway (Pesticide Action Network, 1996). More specifically, it is a potent and specific inhibitor of the enzyme 5-enolpyruvylshikimate 3-phosphate synthase (EPSPS) in plants. This enzyme is the sixth enzyme on the shikimate pathway and it is essential for the biosynthesis of aromatic amino acids and other aromatic compounds in algae, higher plants, bacteria, fungi, and apicomplexan parasites (US EPA, 1993, 2006a). The shikimate pathway is absent in mammals. "Glyphosate is particularly effective

because most plants metabolically degrade it very slowly or not at all, and it translocates well to metabolically active tissues such as meristems” (Cerdeira and Duke, 2006).

Essentially cultivation of GT alfalfa and conventional alfalfa are the same, except GT alfalfa has the ability to tolerate an in-crop glyphosate treatment. Herbicides related to alfalfa farming can be divided into two major groups. One group includes herbicides that do not kill alfalfa (e.g., 2,4-DB, benefin, bromoxynil, clethodim, diuron, *S*-ethyl dipropyl(thiocarbamate) (EPTC), hexazinone, imazamox, imazethapyr, metribuzin, norflurazon, paraquat, pronamide, sethoxydim, terbacil, and trifluralin), and are, therefore, used to control weeds in alfalfa. The other group includes herbicides that kill alfalfa (e.g., 2,4-D, dicamba, clopyralid, and picloram), so they are used for stand removal. It should be noted that adoption of GT alfalfa may increase use of some herbicides used for stand removal. For stand removal adoption of GT alfalfa may result in a shift from glyphosate to other herbicides. Herbicide shifts due to stand removal would be smaller in magnitude than herbicide shifts due to weeds control.

### 1.3 Herbicide Usage as Related to GT Crops

A controversy exists over whether herbicide usage has increased as a result of GT crops first adopted in 1996. A few studies have claimed that the volume of herbicide use is greater due to GT crops (Benbrook, 2004). While other studies demonstrate a decrease of overall herbicide usage related to the increased use of herbicide resistant crops, more details discussed below (Fernandez-Cornejo, 2006; Gianessi and Reigner, 2006; Sakula, 2006; Johnson et al., 2008; Hiemlich et al., 2000). Benbrook (2004) evaluated the USDA National Agricultural Statistics Service (NASS) data on genetically engineered (GE) crop acreage along with data on pesticide volumes used, from 1996 to 2004, and determined that GE corn, soybeans and cotton have led to a 138 million pound increase in herbicide use since 1996, which is a 5% increase. Benbrook (2004) attributes this increase to increasing weed resistance to glyphosate and reduction in glyphosate prices after the patent expired. Benbrook (2004) concluded that across all crops, GE crops reduced pesticide use from 1996 to 1998, but from 1999 to 2004, pesticide use increased.

The NASS data does not directly report amount of herbicide applied based on conventional versus GE varieties. NASS pesticide surveys report the percent of acres treated with a given pesticide, the average rate of application (for each distinct application), the average number of applications, the rate per crop year (average one-time rate multiplied by the number of applications), and the total pounds applied. NASS also reports total acres planted to corn, soybeans, and cotton by year and the percent of acres planted to various genetically modified crops. Using these two sources of data, Benbrook (2004), estimated herbicide use on conventional versus herbicide resistant crops using the following equation:

$$\frac{\text{Average herbicide rate (pounds per acre) for all acres of crop X} - \left[ \text{\% acres HT varieties for crop X} \times \text{Rate herbicide application (pounds per acre) on HT crop X} \right]}{\text{\% acres non-HT varieties of crop X}} = \text{Herbicide Pounds Applied per Acre of Non-HT Variety of Crop X}$$

The “rate of herbicide application in herbicide-tolerant acres” was estimated using NASS pesticide use data, coupled with information from herbicide manufacturers and universities.

At the request of Benbrook Consulting Services, USDA Economic Research Service (ERS) reported for only 1998, both the percent of total soybean acreage by category (conventional varieties, no glyphosate applied; conventional varieties, glyphosate applied (mostly on no-till acreage); Roundup Ready® varieties; and other HT varieties), as well as the average number of herbicides and pounds of herbicides applied in each category. The average acre of herbicide-tolerant soybeans in 1998 was treated with 0.07 pounds more herbicide than conventional acres. Benbrook’s (2004) summary is presented in figure N-1.

**Figure N-1: Annual percent change in pesticide use after introduction of genetically modified crops, 1996-2004 (Benbrook, 2004)**

On the other hand, others, such as Heimlich et al. (2000) have indicated there has not been a significant increase in the amount of herbicide usage since emergence of GT crops. Heimlich et al. (2000) noted that using glyphosate has resulted in the replacement of herbicides that are at least three times as toxic and persist almost twice as long as glyphosate, Gianessi and Carpenter (2000) had similar conclusions. Trewavas and Leaver (2001) conducted an analysis which revealed that 3.27 million kg of other herbicides have been replaced with 2.45 million kg of glyphosate in soybean fields in the U.S. Carpenter and Gianessi (2003) concluded that the introduction of GT soybeans has resulted in a decrease in the total volume of herbicides used. However, Gianessi’s (2005) calculations indicate that if GT sugar beets were adopted, reduction in herbicide use would not be as great as for combined GT crops, because the herbicides used now in non-transgenic sugar beets are mainly low use rate compounds in the U.S.

Gianessi and Reigner, 2006 noted that an increase in glyphosate usage coincided with a decrease in aggregate amount of herbicides by 61 million pounds (of active ingredient) between 1997 and 2002. Much of this reduction occurred in cotton and soybeans, where several herbicides were replaced by glyphosate (million lbs. reduction): bentazon (-4.4), disodium methanearsenate (DSMA) (-0.8), fluometuron (-4.5), imazethapyr (-1.0), metribuzin (-1.5), methylarsonic acid, sodium salt (MSMA) (-1.7), paraquat (-2.9), pendimethalin (-14.0), sethoxydim (-1.1), and trifluralin (-13.0). R/S Metolachlor, which accounted for 67 million pounds of herbicide use in 1997, was voluntarily withdrawn from the market prior to 2002, but S-Metolachlor replaced it on the market. Glyphosate was adopted on many soybean acres that were previously treated with metolachlor. Cyanazine was also voluntarily withdrawn from the market prior to 2002 and replaced with glyphosate for use on cotton and corn. Corn producers replaced cyanazine with

the following herbicides along with glyphosate: mesotrione, rimsulfuron, and simazine (Gianessi and Reigner, 2006).

Gianessi and Reigner (2006) used NASS data as did Benbrook (2004); however, Gianessi and Reigner (2006) supplemented the NASS data with the National Pesticide Use Database (NPUD), which is based on the following:

- Surveys by the NASS [2,631 records]
- USDA Crop Profiles/Strategic Management Plans [657 records]
- State of California Department of Pesticide Regulation [1,054 records] - The State of California requires full reporting of pesticides used in agriculture.
- Survey of Extension Service Specialists [4,830 records]
- Other Sources [538 records] - Mint Industry Research Council, Cranberry Institute, U.S. Hop Plant Protection Committee, Oregon Hop Commission, and the New England Vegetable and Berry Growers Association. Estimates for statewide aggregations for Arizona and Nevada. Individual survey reports prepared at the state-level were available for certain crops in several states: Nebraska, Washington, North Dakota, Georgia and Virginia.
- Assignments [567 records] - In cases where usage profiles for a crop in a state were Not reported from the above sources, usage estimates were assigned by assuming that a state's pesticide use profile for an active ingredient/crop combination is similar to that of a nearby state.

According to the NPUD (Gianessi and Reigner, 2006) data presented in table N-2 below, the same conclusion made by Gianessi and Reigner can be drawn; however, the data also illustrates the usage patterns of alfalfa. There is an increase in glyphosate from 1992 which predates the first GT crops used in 1996, this increase causes an overall increase on herbicides; however, when glyphosate is removed from the total herbicide used there is a 30% reduction when looking at herbicides commonly used on alfalfa. Other interesting findings are the increases in clethodim, clopyralid, and hexazinone; however, this increase does not correlate to the introduction of GT alfalfa (application rates of total herbicides on alfalfa was relatively the same from 1992, 1997, and 2002). Additionally, regardless of their increase the aggregate herbicide usage still shows a decrease.

**Table N-2. Alfalfa Herbicide Use Data (Gianessi and Reigner, 2006)**

| Herbicide                       | 1992             | 1997        | 2002        | Percent Difference<br>(1992 to 2002) |
|---------------------------------|------------------|-------------|-------------|--------------------------------------|
|                                 | Lbs a.i. applied |             |             |                                      |
| Glyphosate                      | 16,793,371       | 34,817,639  | 102,325,419 | +509                                 |
| 2,4-D                           | 41,938,491       | 40,589,955  | 40,071,957  | -4                                   |
| 2,4-DB                          | 980,980          | 603,975     | 522,486     | -47                                  |
| Benefin                         | 478,205          | 161,983     | 104,880     | -78                                  |
| Bromoxynil                      | 3,444,727        | 2,920,222   | 2,058,153   | -40                                  |
| Clethodim                       | 80,003           | 670,721     | 619,944     | +675                                 |

| Total Herbicide Used on Alfalfa | 4,921,532        | 3,960,058   | 4,325,029   | -12                                  |

NASS data was independently evaluated for this technical report for the purpose of examining herbicide use trends in glyphosate-tolerant crops (corn, cotton, soybeans and wheat) since 1996. Glyphosate usage in these crops was also examined. The data is inconsistent across crops and years, but a general trend of increased glyphosate usage can be seen (See figures N-2 and N-3), while a general decrease in other herbicide use can be seen for three other herbicides common to alfalfa (See figures N-4, N-5, and N-6). The exact trend depends on crop and herbicide, as well as weather but overall a decrease in other herbicide use on alfalfa and reported crops can be seen. The actual pounds of glyphosate applied per crop are listed in table N-3, with the percent increase given.

**Figure N-6: Trifluralin use in cotton and soybeans, 1996-2006**

**Table N-3. Glyphosate Use in Corn, Cotton, Soybeans, and Wheat, 1996-2006**

| Crop    | Thousand Pounds Applied (Year) |               | Percent Difference (%) | Thousand Pound Difference |
|---------|--------------------------------|---------------|------------------------|---------------------------|
| Corn    | 1,878 (1996)                   | 11,913 (2003) | 634                    | 10,035                    |
| Cotton  | 3,045 (1997)                   | 14,540 (2005) | 478                    | 11,495                    |
| Soybean | 8,687 (1996)                   | 91,640 (2006) | 1,055                  | 82,953                    |
| Wheat   | 1,421 (1996)                   | 8,215 (2006)  | 578                    | 6,794                     |

Overall, herbicide use in the United States shows a downward trend between 1995 and 2002, especially in corn (Fernandez-Cornejo, 2006). Figure N-7 from the USDA ERS Agricultural Resources and Environmental Indicators (AREI) report presents herbicide application rates in corn, cotton, and soybean from 1995 to 2002.

**Figure N-7: Pesticide use in major field crops (Fernandez-Cornejo, 2006)**

Sankula (2006) evaluated the impact of biotechnology-derived crops planted in the United States in 2005. A summary of the herbicide analysis follows:

- Herbicide-tolerant canola used less herbicide active ingredient per acre than conventional canola, which represented a reduction of 0.69 million pounds of herbicide use in 2005.
- Herbicide-tolerant corn reduced herbicide use in corn by 21.8 million pounds in 2005, which corresponds to a grower cost savings of \$269 million. Compared to 2004, grower returns were 94% higher and pesticide use was 18% lower due to a 67% increase in the adoption of herbicide resistant corn (due to EU approvals).
- Herbicide-tolerant cotton reduced pesticide use by 18 million pounds and reduced production costs by \$39 million.
- On average GT soybean programs used 1.03 pounds active ingredient per acre (lbs a.i./A) whereas conventional herbicide programs used an additional 0.32 lb a.i./A. This translates to a reduction of 39.4 million pounds of herbicide and a cost savings of \$134 million.

Johnson et al. (2008) evaluated the NASS database and concluded that herbicide use in 2006 was reduced by 100.5 million pounds of active ingredient based on estimates of biotechnology-derived crop replacement of conventional crops.

No calculations or speculation on GT alfalfa's impact on herbicide usage have been published. In 2005, when GT alfalfa was introduced commercially, only 0.2% of the total harvested alfalfa was GT alfalfa. In 2006, 3 million pounds of seed was made available for planting. Without reliable estimations on the market share of GT alfalfa estimating the increase in herbicides and glyphosate residue on the following assumptions:

- 90% of alfalfa acreage (Based on Sankula, 2006 using highest adoption herbicide-resistant crops, whereas, 88% national acreage of soybeans are herbicide-resistant)

- Annual USDA Crop Report 2007's alfalfa national acreage of 21,670,000 (USDA, 2008)
- Highest application of glyphosate allowed per year on GT crops of 7.32 pounds (see section 2.1 for details)

Therefore if the highest end application rate is used on the 19,503,000 acres glyphosate's highest estimation of usage would be 142,761,960 pounds. However 143 million pounds of glyphosate is an estimation of the potential amount of glyphosate due to adoption of GT alfalfa. As stated previously only 0.2% of the total harvest in 2005 was GT; however, glyphosate usage was not recorded. Glyphosate usage on GT crops would be dependant on the weather conditions, weed profile, and various other uncontrolled factors. This report will try to predict the environmental risks of the potential increase in glyphosate as well as comparing the risks of the 20 other herbicides used on alfalfa.

#### 1.4 Glyphosate Resistant Weeds Due to GT Alfalfa Cultivation

Weeds can develop resistance to herbicides for the following reasons: frequent exposure to a particular herbicide, the spread of naturally resistant weed seeds, and the outcrossing of herbicide-tolerant genes from genetically altered plants to weedy relatives. Certain weeds have become resistant to the herbicide glyphosate. Further details on glyphosate resistant weeds; refer to technical reports *Effects of Glyphosate-Resistant Weeds in Agricultural Systems* (appendix G) and *Effects of Glyphosate-Resistant Weeds in Non-Agricultural Ecosystems* (appendix H).

Although more recent figures are not reported, in 1998, a University of Wisconsin weed control specialist reported that herbicides are applied to less than 17 percent of U.S. alfalfa hay acreage (Wilke, 1998). Providing the option of spraying herbicides directly over alfalfa is likely to increase the amount of chemicals used in alfalfa production. In fact, the National Center for Food and Agriculture Policy estimates that GT alfalfa could result in the application of 200,000 pounds more herbicides per year in California alone (Hubbard, 2008).

Proper crop and weed management practices should be followed and the risk of glyphosate resistant weed development. Increased exposure to one herbicide, namely glyphosate, may cause a shift in glyphosate resistant weeds, and potential for weeds developing glyphosate resistance. Diversifying weed control tactics can delay herbicide resistance development and aid in controlling herbicide-resistant weeds, thus, preserving the herbicide efficacy. Using differing mode of action herbicides will decrease the chance of plants developing resistance to a single herbicide. GT crops should be rotated with non-GT crops to reduce the heavy reliance on glyphosate, thus, decreasing the risk of weeds developing resistance to glyphosate. Where no-till practices are in use, heavy tillage is another mitigation method to eradicate a glyphosate resistant weed. The Herbicide Resistance Action Committee (HRAC) is a consortium of agrochemical manufacturers that provides information about resistance cases and strategies for management (HRAC, 2002). US EPA and the Pest Management Regulatory Agency of Canada (PMRA) have worked closely with the HRAC and the Weed Science Society of America (WSSA) to address herbicide resistance. US EPA and Canada have developed voluntary resistance management guidelines based on rotation of herbicides based on mode of action for all agricultural use of pesticides (Canada PMRA 1999; US EPA 2001).

In the event of glyphosate resistant weeds, the management practices suggested are to use the following less-resistant prone herbicides recommended for use: paraquat/diquat, MSMA, phenoxy herbicide (e.g., 2,4-D, MCPA, trichlopyr, dicamba), tubulin inhibitors (e.g., benefin, fluchloralin, pendimethalin, ethanlfluralin, trifluralin), triazine (amitrole, atrazine, cyanazine, simazine, trietazine, metribuzin), bromoxynil, s-ethyl dipropylthiocarbamate (EPTC), imazamox, imazethapyr, sethoxydim, clethodim, glufosinate, and/or rare protox herbicides (acifluorfen). A list of glyphosate-tolerant weeds and suggested herbicides are presented in appendix N-4 of this technical report; however, the list is not exhaustive due to new weeds being registered or discovered regularly. These herbicides are more toxic and persistent in the environment, thus, they may exert a greater environmental impact; however, weed management is plant specific. In some cases of a multiple herbicide resistance, the preferred weed management practice is deep tillage. Currently, glyphosate resistant weeds have taken over two million acres of farmland in the U.S. (Hubbard, 2008). The spread of glyphosate resistant weeds has outpaced the development of new tools for controlling them, leaving farmers with few options for dealing with thousands of acres of “superweeds” that glyphosate cannot eliminate. Some of the resistant weeds also produce copious amounts of seeds, which can lay dormant in the soil for many years and germinate later on down the road, further compounding the problem of glyphosate resistant weeds and complicating the containment efforts by farmers. The most problematic glyphosate resistant weeds in the U.S. include pigweed (waterhemp), horseweed (marestail), common and giant ragweed, and ryegrass (Hubbard, 2008).

## 1.5 Methodology

In efforts to assess the potential impacts to wildlife, amphibians, plants, and ecosystems from increased glyphosate and other chemical usage due to the deregulation of GT alfalfa by USDA in 2005, a Tier 1 ecological risk assessment was conducted for glyphosate usage on GT alfalfa. In the preparation of this risk assessment, literature searches of glyphosate were conducted in the open literature using the literature search strategy presented in appendix N-2 of this technical report. Several DIALOG databases were searched. EPA’s Ecotox Database was searched for data on glyphosate (<http://cfpub.epa.gov/ecotox/>); the data tables generated are considerably large; therefore, the data were mined for missing toxicity data when needed and referenced in the toxicity tables as needed. Google and Google Scholar search engines supplemented the DIALOG search. References were selected from the extensive list of literature based on requesting the abstracts and determining if the data were not included in the four below ecological risk assessments or provided contrary or controversial information to these four highly reviewed ecological risk assessments. Primary sources of data were obtained from the following three documents: the US EPA’s 1993 Reregistration Eligibility Decision (RED) document on glyphosate (US EPA, 1993); the US EPA’s 2006 Glyphosate New Use (bent-grass): Environmental Fate and Effects Risk Assessment (US EPA, 2006a), the US EPA’s Glyphosate Human Health Risk Assessment for Proposed Use on Indian Mulberry and Amended Use on Pea, Dry. (US EPA, 2006c); the USDA, Forest Service 2003 human health and ecological risk assessment on glyphosate (USDA, 2003); and an ecotoxicological risk assessment for Roundup herbicide by John P Giesy and colleagues in 2000 (Giesy et al., 2000). Additional information was used from a risk assessment on the use of glyphosate by Monsanto (Honegger et al., 2008 ; Mortensen et al., 2008, Priester et al. 2007, 2008)

This ecological risk assessment presented is not a comprehensive summary of all of the available information and does not cite all of the available literature. As USDA determined in 2003, an all inclusive and detailed review of each ecotoxicological study would tend to obscure rather than inform. Therefore this document relies on the information that is likely to impact the risk assessment.

The application rate of glyphosate on GT alfalfa was determined by reviewing all the glyphosate herbicide formulations that report the maximum daily and yearly use rate on GT alfalfa. These formulations are all Monsanto Company products, as GT alfalfa is also a Monsanto product. It can be expected that other formulations for glyphosate herbicide could and may be used on GT alfalfa; however, to develop the quantitative risk assessment the maximum use rate was 1.99 lb a.e./acre for a single use, with minimum reapplication within 7 days and not to exceed 7.98 lb a.e./acre in a year. The legal maximum single use rate for glyphosate on GT alfalfa is 1.55 lb a.e./acre, with minimum reapplication within 7 days and not to exceed 5.96 lb a.e./acre in a year. Thus, the risk assessment conducted is a particularly conservative one.

## 2.0 Chemical Description and Commercial Formulations Glyphosate Herbicide

Glyphosate is a substituted glycine, the simplest amino acid. The glyphosate molecule has a methylphosphono group bonded to the nitrogen atom of the amino group of glycine as denoted in figure N-8 below.

Figure N-8: Glyphosate molecular structure

Physical and chemical properties of glyphosate are in table N-4 below.

Table N-4. Physical and Chemical Properties of Glyphosate

| Property                                      | Value                                                                                    | Source       |

Glyphosate salts serve as the source of *N*-(phosphonomethyl)glycine. Several salts of glyphosate with different counter cations are currently marketed. Each salt has a different “glyphosate equivalent”, which is defined as the ratio of the molecular weight of *N*-(phosphonomethyl)glycine to the molecular weight of the salt. GT alfalfa has the following approved glyphosate herbicides approved for use in table N-5. GT alfalfa could tolerate other herbicide formulations with glyphosate; however, the five products listed below are the herbicides approved for use on GT alfalfa.

**Table N-5. End Use Products Approved for Use on GT Alfalfa**

| <b>Product Name</b>   | <b>% Salt</b> | <b>Glyphosate salt CAS No.</b>    | <b>USEPA PC Code</b> | <b>Surfactant</b>                                    | <b>Manufacture</b> |

## 2.1 Application Rate Specific to GT Alfalfa

The Honcho and Honcho Plus products contain 41% of the isopropylamine salt of glyphosate, equivalent to 3 lbs of glyphosate equivalents per gallon (356 g glyphosate/L). The product is to be applied as over-the-top (spot treatment; broadcast ground application) for pre-plant, preemergence, and post-emergence uses. For the risk assessment, the maximum total application rate of 7.98 glyphosate equivalents per acre per year (2.6 gal of product per acre), with single use maximum applications of 1.99 lbs glyphosate a.e./acre. The minimum reapplication interval is 7 days. The maximum label rate for a single application of glyphosate to GT alfalfa is 1.55 lbs glyphosate a.e./acre, and the maximum total application rate for the year is 5.96 lbs glyphosate a.e./acre.

The Roundup Ready Original MAX®, Roundup WeatherMAX®, and Roundup Ultra MAX II® products contain 48.8% of the phosphate salt of glyphosate, equivalent to 4.5 lbs of glyphosate equivalents per gallon (540 g glyphosate/L). The product is to be applied over-the-top (spot treatment; broadcast ground application) for pre-plant, preemergence, and post-emergence uses. The maximum total application rate is 7.32 glyphosate equivalents per acre per year (2.4 gal of product per acre), with a single use maximum application of 1.90 lbs glyphosate/acre. The minimum reapplication interval is 7 days. The maximum label rate for a single application of glyphosate to GT alfalfa is 1.55 lbs glyphosate a.e./acre, and the maximum total application rate for the year is 5.96 lbs glyphosate a.e./acre.

## 2.2 Residue of Glyphosate on Crops and Livestock

Studies with a variety of plants indicate that uptake of glyphosate or AMPA from soil is limited. Foliar-applied glyphosate is readily absorbed and translocated throughout the trees or vines to the fruit of apples, coffee, dwarf citrus (calamondin), pears and grapes (US EPA, 2006c). For the most part, the ratio of glyphosate to AMPA is 9 to 1 but can approach 1 to 1 in a few cases (e.g., soybeans and carrots). Much of the residue data for crops reflects a detectable residue of parent glyphosate (0.05 - 0.15 ppm) along with residues below the level of detection (<0.05 ppm) of AMPA (US EPA, 2006c). EPA determined that, based on toxicological considerations, AMPA need not be regulated and should be dropped from the tolerance expression (US EPA, 2006c). Metabolism studies submitted for genetically engineered GT canola and GT corn have

indicated that metabolism in GT plants is essentially the same as that in normal plants (US EPA, 2006c). During a confined crop rotational study the residues of glyphosate were undetected 30 days after treatment (US EPA, 2006c).

Studies with lactating goats, laying hens, rats, rabbits, and cows fed a mixture of glyphosate and AMPA indicate that the primary route of elimination is by excretion (urine and feces). The residues in eggs, milk, and livestock tissues are glyphosate and its metabolite AMPA; there was no evidence of further metabolism in these animals (US EPA, 2006c).

## 2.3 Summary of Findings

At ambient temperatures, glyphosate is a white crystalline substance that is not volatile with high water solubility. In the crystalline form, glyphosate has both positive and negative regions, these dipolar ion species are sometimes referred to as a zwitterion. In aqueous solutions, the hydrogen atoms of the carboxylic acid (COOH) and phosphate (PO<sub>2</sub>H<sub>2</sub>) groups may be associated or dissociated depending on the pH of the solution. These dipolar ion species are the regions expected to bond to carbon containing molecules in the soil as discussed further in Chapter 3. Glyphosate is in a liquid form for herbicide formulations; generally, the composition of the herbicide is considered a trade secret. One formulation of glyphosate, Honcho®, has a tallow amine surfactant (Monsanto, 2007a). This and other surfactants are added to the herbicide formulations to increase leaf penetration. The maximum single use application of 1.99 lbs glyphosate/acre was based on Honcho and Honcho Plus products containing 41% of the isopropylamine salt of glyphosate, equivalent to 3 lbs of glyphosate equivalents per gallon (356 g glyphosate/L). This application rate and a minimum reapplication period of 7 days was used to estimate high-end use on GT alfalfa in efforts to quantify the risk to ecological organisms.

### 3.0 Glyphosate and Alfalfa Herbicide Fate in the Environment and Occurrence

#### 3.1 Glyphosate Fate

The environmental fate assessment is based on the US EPA's 1993 RED document on glyphosate (US EPA, 1993); the US EPA's 2006 Glyphosate New Use (bent-grass): Environmental Fate and Effects Risk Assessment, USDA, Forest Service 2003 human health and ecological risk assessment on glyphosate (USDA, 2003); an ecotoxicological risk assessment for Roundup herbicide by John P Giesy and colleagues in 2000 (Giesy et al., 2000), and recent relevant open literature studies related to the behavior of glyphosate in the environment.

Glyphosate has a low vapor pressure and Henry's law constant; thus, it has a low potential to volatilize from soil and water. Glyphosate is hydrophilic, with a low *n*-octanol-water partition coefficient; therefore, it has low potential to bioaccumulate in animals. It has a high solubility in water and does not undergo hydrolysis or photolysis. Due to glyphosate's strong adsorptive quality to soil, it is not expected to contaminate groundwater; however, runoff water could contain particulates with adsorbed glyphosate. The chemical fate properties of glyphosate are presented in table N-6 below.

**Table N-6. Chemical Fate Properties of Glyphosate**

| Property                                                                          | Value                                                                                                                     | Source              |
|-----------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------|---------------------|
| Common Name                                                                       | Glyphosate                                                                                                                | US EPA, 2006a, 1993 |
| Chemical Name                                                                     | <i>N</i> -(phosphonomethyl)glycine                                                                                        |                     |
| Log Kow                                                                           | -3                                                                                                                        |                     |
| Hydrolysis                                                                        | Stable ≥30 days at pH 3, 6, and 9 at 5 and 35°C                                                                           |                     |
| Photolysis                                                                        | Does not absorb light energy pH 5, 7, and 9                                                                               |                     |

In soil, sediment, or natural water, microbes degrade glyphosate quickly and the major metabolite is aminomethyl phosphonic acid (AMPA) which is further degraded to CO<sub>2</sub>, although at a slower rate than the parent glyphosate (US EPA, 2006a, 1993). Figure N-9 presents the chemical structure of AMPA.

**Figure N-9: Chemical structure of AMPA**

In the environmentally significant pH range of 5 to 9, the first phosphonic and carboxylate protons are fully dissociated. The dissociation of the second phosphonic proton increases above a pH of 6, but the amine proton is unlikely to dissociate in the environment.

The molecule of glyphosate can be envisioned as a ligand that binds via the oxygen atoms. These molecular characteristics of glyphosate have major implications in its mode of herbicide action and in the sorption behavior of glyphosate on soils.

In field studies (including soils) conducted in the coldest climates (i.e., Minnesota, New York and Iowa) were the longest and ranged from about 29 days up to about 140 days, indicating that glyphosate residues in the field are somewhat more persistent in cooler climates as opposed to milder ones (Georgia, California, Arizona, Ohio, and Texas). Also, glyphosate was shown to remain predominantly in the 0-6 inch soil layer at all field sites in one study.

### 3.2 Alfalfa Other Herbicide Comparative Fate Data

Sixteen herbicides are used on alfalfa and four are used to remove GT alfalfa fields. Table N-7 below has compiled environmental fate data on these twenty herbicides for the herbicides respective EPA RED documents, MSDSs, or PAN Pesticides Database. In general most of the 20 herbicides as compared to glyphosate are more persistent in the soil and more apt to bioaccumulate. In section 5.2 a comparison of the environmental impact of these herbicides via an indicator known as the Environmental Impact Quotient (EIQ) is made.

#### 3.2.1 Hydrolysis Alfalfa Herbicide Comparison Data

Most herbicides (2,4-D, 2,4-DB, benefin, clethodim, dicamba, diuron, EPTC, hexazinone, metribuzin, norflurazon, imazethapyr, picloram, picloram, sethoxydim, and terbacil) were stable to hydrolysis, including glyphosate. Bromoxynil was unstable at higher pHs (US EPA, 1998a);

sethoxydim was slightly unstable at lower pHs with a 9 day half-life at pH 5 (US EPA, 2005c). Four herbicides (imazamox, clopyralid, imazethapyr, and pronamide) had missing hydrolysis data. Details are in table N-7.

### *3.2.2 Photolysis Alfalfa Herbicide Comparison Data*

#### *3.2.2.1 Aqueous*

Seven herbicides were stable (>30 days: clopyralid, dicamba, diuron, EPTC, hexazinone, paraquat, and terbacil) to aqueous photolysis, including glyphosate. Six herbicides (2,4-D, 2,4-DB, bromoxynil, imazamox, norfluzaon, and picloram) were stable for 1 to 30 days in water. At least five herbicides (benefin, metribuzin, imazethapyr, sethoxydim, and trifluralin) were unstable and underwent photolysis in less than 48 hours. Three herbicides (clethodim, imazethapyr, and pronamide) had missing data. Details are in table N-7.

#### *3.2.2.2 Soil*

Many herbicides were stable (>30 days; 2,4-D, 2,4-DB, clopyralid, dicamba, diuron, EPTC, hexazinone, imazamox, imazethapyr, paraquat, picloram, pronamide, terbacil, and trifluralin) to soil photolysis, including glyphosate. Two herbicides (benefin and norfluzaon) were stable for 7 to 30 days in soil to photolysis. At least three of the herbicides (bromoxynil, metribuzin, and sethoxydim) underwent photolysis in less than 7 days. Three herbicides (metribuzin, clethodim, and imazethapyr) had missing data. Details are in table N-7.

### *3.2.3 Soil Metabolism Alfalfa Herbicide Comparison Data*

#### *3.2.3.1 Aerobic Soil*

Many herbicides had greater than 30 day half-lives in aerobic (benefin, clopyralid, diuron, EPTC, hexazinone, imazamox, imazethapyr, metribuzin, norfluzaon, paraquat, picloram, pronamide, terbacil, and trifluralin) soils. Six herbicides had a short half-life of <30 days in aerobic soil metabolism studies, including glyphosate (2,4-D, 2,4-DB, bromoxynil, clethodim, dicamba, and sethoxydim). All herbicide had aerobic soil metabolism data.

#### *3.2.3.2 Anaerobic Soil*

Many herbicides were stable in anaerobic soils (2,4-DB, dicamba, diuron, EPTC, hexazinone, imazamox, imazethapyr, metribuzin, paraquat, picloram, pronamide, sethoxydim, terbacil, and trifluralin) with greater than 30 day half lives and three herbicides (benefin, bromoxynil, and clethodim) with a short half life (<30 days) in anaerobic soil. Three anaerobic soil metabolism data (2,4-D, clopyralid, and glyphosate) were missing. Details are in table N-7.

### *3.2.4 Aquatic Metabolism Alfalfa Herbicide Comparison Data*

#### *3.2.4.1 Aerobic*

Many herbicides had missing data concerning aquatic metabolism for aerobic (benefin, clethodim, clopyralid, dicamba, EPTC, imazamox, imazethapyr, metribuzin, picloram, pronamide, terbacil, and trifluralin) systems. Some had greater than 30 day half-lives in aerobic (diuron, hexazinone, norfluzon) water tests. Three herbicides had a short half-life of <7 days in aerobic soil metabolism studies (bromoxynil, glyphosate, and sethoxydim). Four aerobic water metabolism studies on herbicides had a range of 1 week to a month half-lives (2,4-D, 2,4-DB, and paraquat). Details are in table N-7.

#### 3.2.4.2 Anaerobic

Many herbicides had missing data concerning anaerobic aquatic metabolism for anaerobic (bromoxynil, clethodim, clopyralid, dicamba, EPTC, imazamox, imazethapyr, metribuzin, paraquat, terbacil, and trifluralin). Some had greater than 30 day half-lives in anaerobic (diuron, hexazinone, norfluzon, picloram, and sethoxydim) water tests. Two herbicides (benefin and glyphosate) had a short half-life of >7 days in anaerobic soil. Two anaerobic water studies had a range of 1 week to a month half-lives (2,4-D and 2,4-DB). Details are in table N-7.

### 3.2.5 Soil Mobility Alfalfa Herbicide Comparison Data

Thirteen herbicides had a very low adsorption coefficient <1, suggesting they are highly mobile in the soil (bromoxynil, clopyralid, hexazinone, imazethapyr, metribuzin, picloram, pronamide, sethoxydim, and terbacil). One herbicide had soil adsorption coefficient between 1 and 50 (norfluzon). Four herbicides including glyphosate had limited or low mobility (>50 soil adsorption coefficient; benefin, imazamox, paraquat, and trifluralin), four herbicide had missing data on soil mobility (clethodim, dicamba, diuron, and EPTC). Details are in table N-7.

### 3.2.6 Soil Water Partition Coefficient ( $K_d$ ) Alfalfa Herbicide Comparison Data

Most of the soil water partition coefficient ( $K_d$ ) for herbicides used in alfalfa were missing (benefin, clethodim, clopyralid, dicamba, imazamox, imazethapyr, metribuzin, norfluzon, picloram, pronamide, sethoxydim, and terbacil). Three herbicides had >10 coefficients (diuron, glyphosate, and paraquat), five had moderate to mobile soil water partition coefficients of 0-10 (2,4-D, 2,4-DB, bromoxynil, EPTC, and hexazinone). The  $K_d$  value is simply a ratio of the sorbed phase concentration to the solution phase concentration at equilibrium and based more on surface area than organic matter; thus, lower numbers mean a higher affinity for the aqueous phase rather than suspended particulate matter. Details are in table N-7.

### 3.2.7 Soil Adsorption Coefficient ( $K_{oc}$ ) Alfalfa Herbicide Comparison Data

The  $K_{oc}$  is the partition coefficient of the herbicide in the organic fraction of the soil. The higher the value the more likely the compound is bound tightly to carbon rich soil. Only two herbicides had a lower than 10 partition coefficient, dicamba and hexazinone. Ten herbicides had >10 partition coefficients (2,4-D, 2,4-DB, benefin, bromoxynil, clethodim, diuron, EPTC, glyphosate, imazethapyr, picloram, and terbacil), whereas seven had missing data (clopyralid, imazamox, metribuzin, norfluzon, paraquat, pronamide, and sethoxydim). Details are in table N-7.

### *3.2.8 Terrestrial Field Dissipation Studies (half-life) Alfalfa Herbicide Comparison Data*

Thirteen herbicides were detected in the soil at least 30 days after application (2,4-D, 2,4-DB, benefin, bromoxynil, diuron, hexazinone, imazamox, imazethapyr, metribuzin, paraquat, picloram, sethoxydim, and terbacil); four herbicides were detected in less than 30 days (bromoxynil, EPTC, glyphosate [except in Iowa study: 140 days], and trifluralin), with five herbicides missing data (clethodim, clopyralid, dicamba, norfluzon, and pronamide). Details are in table N-7.

### *3.2.9 Bioaccumulation*

Five herbicides were found to have the potential to bioaccumulate (clopyralid, EPTC, norfluzon, sethoxydim, and trifluralin). Whereas five herbicides are not expected to bioaccumulate (<1; 2,4-D, 2,4-DB, glyphosate, hexazinone, and terbacil), eleven did not have data (benefin, bromoxynil, clethodim, dicamba, diuron, imazamox, imazethapyr, metribuzin, paraquat, picloram, and pronamide). Details are in table N-7.

#### *3.2.9.1 Aquatic Field Dissipation Studies (half-life) Alfalfa Herbicide Comparison Data*

Four of the twenty herbicides used on alfalfa had aquatic field dissipation studies the half lives were as follows: sethoxydim 1-9 days; glyphosate 7.5 days in water and 120 days in sediment; 2,4-D was stable up to 50 days; and diuron 115 to 177 days. Details are in table N-7.

**Table N-7. Glyphosate and Other Commercial Herbicides – Comparative Environmental Fate Properties**

| Herbicide         | Environmental Fate Properties  |                                |                                                                                                                                 |                                                                                 |                                                                                                                      |                                             |                                           |                                 |                                                                                                                                                                                                                                                     |                                                                |                                                                         |                                          |

### 3.3 Glyphosate and Metabolite Occurrence

In a USDA monitoring study conducted on surface water, groundwater, and soil from 2001 to 2006, the metabolite AMPA was observed more frequently than the parent compound glyphosate (Scribner et al., 2007). The sample collections were from several USGS studies including: the National Stream Quality Accounting Network Program; the National Water-Quality Assessment Program; and the Toxic Substances Hydrology Program. Groundwater samples had measured concentrations of glyphosate, ranging from  $< 0.01$  to  $4.7 \mu\text{g/L}$  (68 detections out of 873 samples), and AMPA, ranging from  $< 0.01$  to  $2.6 \mu\text{g/L}$  (133 detections out of 873 samples). In surface water the range of glyphosate detected was  $< 0.01$  to  $427 \mu\text{g/L}$  (489 detections out of 1262 samples), and the range of AMPA detected was  $0.38$  to  $29 \mu\text{g/L}$  (489 detections out of 1262 samples).

In all of the samples, the maximum detections were from an agricultural ditch basin (Leary Weber ditch of the White River Basin in Indiana). In rainwater collected from the Indiana Leary Weber Ditch Basin, measured concentrations of glyphosate ranged from  $0.02$  to  $1.1 \mu\text{g/L}$  and AMPA ranged from  $0.02$  to  $0.47 \mu\text{g/L}$  in 12 of the 14 samples. Glyphosate detections in precipitation are more likely due to glyphosate associated with dust particles being washed down with rain than to glyphosate dissolved in rain). Soil samples from Indiana Leary Weber Ditch Basin indicate glyphosate and AMPA may persist from year to year with a glyphosate maximum concentration of  $476 \mu\text{g/L}$  (119 detections out of 193 samples) and an AMPA maximum concentration of  $956 \mu\text{g/L}$  (154 detections out of 193 samples) (Scribner et al., 2007); however, the detection of these large quantities may have coincided with a recent rain event and application. “The potential persistence of glyphosate in soils warrants further studies given the potential increase of use due to GT alfalfa” (Scribner et al., 2007).

### 3.4 Summary of Findings

Glyphosate has a low potential to leach to groundwater from the soil due to its rapid microbial degradation and strong soil binding properties (Giesy et al., 2000). In a worst case direct soil application field dissipation studies glyphosate and AMPA were found in the top 6 inches, also indicative of a non-leaching chemical. Glyphosate is applied to the foliage and direct soil contact is not expected unless a spill or recent rain event moves the glyphosate from the leaves to the soil. Due to glyphosate’s strong adsorptive qualities to soil groundwater contamination is not expected, as noted with no more than  $4.7 \mu\text{g/L}$  detected by USGS survey study (Scribner et al., 2007). Evaporation is not a major route of dissipation, nor will glyphosate degrade due to hydrolysis or photolysis; microbial degradation is the primary route of dissipation of glyphosate from most ecosystems regardless of the soil and climatic conditions (Giesy et al., 2000). Glyphosate exposure is also possible due to runoff after a rain soon after application, spray drift, inadvertent direct overspray, or wind transport of soil particulates loaded with adsorbed glyphosate. Glyphosate is not expected to bioaccumulate.

The twenty other pesticides used on alfalfa have varying chemical fates. In general most were more persistent and had higher mobility in soils, making them more apt to continually contaminate surrounding water systems. Few were even considered compounds that could

bioaccumulate (e.g., clopyralid, EPTC, norflurazon, sethoxydim, and trifluralin). In section 5.2 further environmental impacts of these herbicides in comparison to glyphosate will be discussed.

## 4.0 Ecotoxicity of Glyphosate and Glyphosate Commercial Formulations and AMPA

The terrestrial ecosystems potentially at risk include the treated area and areas immediately adjacent to the treated area that might receive drift or runoff (recent rain event after application), and might include other cultivated fields, fence rows and hedgerows, meadows, fallow fields or grasslands, woodlands, riparian habitats, or other uncultivated areas. For US EPA Tier 1 assessment purposes, risk is assessed to terrestrial animals or plants assumed to occur exclusively adjacent to the treated area.

Aquatic ecosystems potentially at risk include water bodies adjacent to, or down stream from, the treated field and might include impounded bodies such as ponds, lakes and reservoirs, or flowing waterways such as streams or rivers. The proposed use sites may be located either near freshwater or saltwater habitats. For uses in coastal areas, an aquatic habitat also includes marine ecosystems including estuaries. For US EPA Tier 1 assessment purposes, risk is assessed to aquatic animals and plants assumed to occur in small, static ponds receiving runoff and drift from treated areas.

<sup>a</sup> Birds are considered surrogates for amphibians (terrestrial phase) and reptiles when no data are available.

<sup>b</sup> Freshwater fish may be surrogates for amphibians (aquatic phase) when no data are available.

Within each of these very broad taxonomic groups, an acute and/or chronic endpoint is selected from the available test data. A complete discussion of all toxicity data available for this risk assessment and the resulting measures of effect selected for each taxonomic group are discussed below.

All available data from US EPA's RED document on glyphosate (1993) and new use risk assessment for bent grass (2006); Giesy and colleagues (2000) risk assessment on glyphosate; USDA (2003) risk assessment on glyphosate for the Forest Service; and public literature on the toxicity of glyphosate to plants and animals were used in this risk assessment. Not all taxonomic groups are surveyed because of US EPA registration of pesticide study guideline limitations. Instead, some animals are used as surrogates for other groups based on the similarity of their

physiology and habitat. Therefore, extrapolation to other taxonomic groups may constitute a source of uncertainty in the ecological risk assessment.

## 4.1 Avian Toxicity

Several acute toxicity tests were conducted on birds for glyphosate and its formulations, as well as were several chronic toxicity tests on glyphosate. No data was available on chronic bird toxicity to glyphosate herbicide formulations. A few toxicity tests were also performed for the glyphosate metabolite aminomethyl phosphonate (AMPA). The toxicity study results are discussed in sections 4.1.1 through 4.1.4.

### 4.1.1 Acute Avian Toxicity to Glyphosate

Acute toxicity in birds was assessed using single-dose, dietary, and reproductive toxicity studies. US EPA's preferred test species is either Mallard duck (a waterfowl) or Bobwhite quail (an upland game bird). The results of acute glyphosate toxicity tests in birds are provided in table N-9 below. Glyphosate toxicity in the Bobwhite quail ranged from a dose required to kill 50 percent of a population of test animals ( $LD_{50}$ ) > 2000 mg/kg to a concentration required to kill 50 percent of a population of test animals ( $LC_{50}$ ) > 6300 mg/kg. The Mallard duck was slightly more toxic ( $LC_{50}$  ranged from >4640 to > 6300 mg/kg). Glyphosate tested as an acid produced similar results in the Bobwhite quail and Mallard duck. No toxicity studies were found testing glyphosate as the IPA salt.

**Table N-9. Acute Avian Toxicity to Glyphosate**

| Study Type<br>(% a.i.)                  | Species        | Results                            | Endpoint                                                                 | Reference          |

#### 4.1.2 Acute Avian Toxicity to Glyphosate Herbicide Formulations

The formulations of glyphosate (Honcho® Herbicide, Honcho® Plus Herbicide, Roundup Original MAX® Herbicide, and Roundup WeatherMAX® Herbicide) produced acute toxicity values between LD<sub>50</sub> > 2,250 mg/kg bw and LC<sub>50</sub> > 5,620 mg/kg diet in the Bobwhite quail. Quail were most sensitive to Roundup Original MAX® Herbicide. Acute toxicity values in the Mallard duck ranged from LC<sub>50</sub> > 4,640 mg/kg diet to > 5,620 mg/kg diet. Mallards were most sensitive to the Roundup Original MAX® and WeatherMAX® formulations.

**Table N-10. Acute Bird Toxicity to Glyphosate Herbicide Formulations**

| Study Type (% a.i.)                                                                                | Species        | Results                                       | Endpoint | Reference          |
|----------------------------------------------------------------------------------------------------|----------------|-----------------------------------------------|----------|--------------------|
| Acute, Single-Dose, (Roundup Original MAX® Herbicide)                                              | Bobwhite quail | LD <sub>50</sub> = > 2,250 mg/kg bw           | Death    | Monsanto, 2006     |
| Acute, Single-Dose, I (Roundup Original MAX® Herbicide [N-(phosphonomethyl)glycine; [glyphosate]]) | Bobwhite quail | LD <sub>50</sub> = > 3,851 mg/kg bw           | Death    | Monsanto, 2006     |

| 5-day, Dietary (Honcho® Herbicide)                                                                 | Mallard duck   | LC <sub>50</sub> = > 5620 mg/kg               | Death    | USDA, 2003         |
| 5-day, Dietary (Honcho® Herbicide)                                                                 | Mallard duck   | LC <sub>50</sub> = > 5,620 mg/kg diet         | Death    | Monsanto, 2007b    |
| 5-day, Dietary (Honcho® Plus Herbicide)                                                            | Mallard duck   | LC <sub>50</sub> = > 5,620 mg/kg diet         | Death    | Monsanto, 2007d    |
| 8-day, Dietary (Roundup)                                                                           | Mallard duck   | LC <sub>50</sub> = > 5620 mg product /kg diet | Death    | Giesy et al., 2000 |
| 5-day, Dietary (Roundup)                                                                           | Zebra Finch    | LC <sub>50</sub> = > 8064 mg product /kg diet | Death    | Giesy et al., 2000 |

#### 4.1.3 Acute Avian Toxicity to AMPA

AMPA administered orally as a single dose to the Bobwhite quail produced LD<sub>50</sub> values of >2250 mg AMPA/kg. Administered in the diet for 8 days to Mallard ducks and Bobwhite quail, resultant LC<sub>50</sub> values were >5620 mg AMPA/kg. The no observed effect concentration (NOEC) for both species was 5620 mg AMPA/kg.

**Table N-11. Acute Avian Toxicity to AMPA**

| Study Type (%a.i.) | Species        | Results                      | Endpoint | Reference          |
|--------------------|----------------|------------------------------|----------|--------------------|
| Oral – single dose | Bobwhite quail | LC <sub>50</sub> >2250 mg/kg | Death    | Giesy et al., 2000 |
| 8 day - Dietary    | Bobwhite quail | LC <sub>50</sub> >5620 mg/kg | Death    | Giesy et al., 2000 |
| 8 day - Dietary    | Mallard duck   | LC <sub>50</sub> >5620 mg/kg | Death    | Giesy et al., 2000 |

#### 4.1.4 Chronic Avian Toxicity

Chronic effect levels of glyphosate (tested as acid) were deduced from long-term (16-17 wk) dietary studies. US EPA's preferred test species is either Mallard duck (a waterfowl) or Bobwhite quail (an upland game bird). The no observed effect concentration (NOEC) for both the mallard and Bobwhite quail was 1000 mg a.e./kg diet.

**Table N-12. Chronic Avian Toxicity to Glyphosate**

| Study Type (%a.i.) | Species        | Results                     | Endpoint             | Reference          |
|--------------------|----------------|-----------------------------|----------------------|--------------------|
| 17-wk, Dietary     | Bobwhite quail | NOEC = 1000 mg a.e./kg diet | Reproductive Effects | Giesy et al., 2000 |
| 16-wk, Dietary     | Mallard duck   | NOEC = 1000 mg a.e./kg diet | Reproductive Effects | Giesy et al., 2000 |

#### 4.1.5 Chronic Avian Toxicity to Glyphosate Herbicide Formulations

No data available on chronic bird toxicity to glyphosate herbicide formulations.

### 4.2 Mammal Toxicity

Several acute toxicity tests were conducted on mammals for glyphosate and its formulations, as well as were several chronic toxicity tests on glyphosate. Further details on mammalian toxicity are addressed in the technical reports with this EIS, *Health and Safety Risks from Increased Glyphosate and Other Chemical Usage on Humans (Exclusive of Field Workers)* (appendix L) and *Health and Safety Risks to Field Workers* (appendix M). No studies were found addressing the chronic toxicity of commercial formulations of glyphosate to terrestrial mammals. The toxicity study results are discussed in sections 4.2.1 through 4.2.4.

#### 4.2.1 Acute Mammal Toxicity to Glyphosate

Acute toxicity in terrestrial mammals was assessed using 21-day subacute oral studies. More in depth discussion of mammalian toxicity can be found in another technical report for this EIS entitled, *Health and Safety Risks from Increased Glyphosate and Other Chemical Usage on Humans (Exclusive of Field Workers)* (appendix L). All of the acute toxicity (2,000 to 6,000

mg/kg and acute oral intraperitoneal) studies in rodents for glyphosate are slightly toxic to practically non-toxic, and a non-sensitizer. The results of the acute glyphosate toxicity studies in terrestrial mammals including the goat, rabbit, rat, and hopping mouse and are summarized in table N-13 below. Acute oral LD<sub>50</sub>s for mammals range from 2,047 to > 5,000 mg a.e./kg/ day (d) for glyphosate. Glyphosate tested as IPA salt produced an acute oral LD<sub>50</sub> of 5,700 mg a.e./kg/d in the goat. No studies were reviewed with glyphosate tested as an acid.

**Table N-13. Acute Mammalian Toxicity to Glyphosate**

| Study Type (% a.i.)                  | Species | Results                                 | Endpoint                                                                 | Reference                          |

#### 4.2.2 Acute Mammalian Toxicity to Glyphosate Herbicide Formulations

In glyphosate herbicide formulations, the acute oral LD<sub>50</sub> was 4,860 mg product/kg/d. The No Observed Adverse Effects Level (NOAEL) for the hopping mouse was 16,000 mg product/kg diet. The results are presented in table N-14 below.

**Table N-14. Acute Mammalian Toxicity to Glyphosate Herbicide Formulations**

| Study Type (% a.i.)      | Species       | Results                                                                               | Endpoint           | Reference          |
|--------------------------|---------------|---------------------------------------------------------------------------------------|--------------------|--------------------|
| Acute, Oral (Roundup)    | Goat          | LD <sub>50</sub> = 4,860 mg product /kg/d<br>NML <sup>b</sup> = 2,100 mg product/kg/d | Death              | Giesy et al., 2000 |
| 4-day, Dietary (Roundup) | Hopping Mouse | NOAEL = > 16,000 mg product/kg diet                                                   | NOAEL <sup>a</sup> | Giesy et al., 2000 |
| 4-day, Dietary (Roundup) | Hopping Mouse | NOAEL = > 16,000 mg product/kg diet                                                   | NOAEL <sup>a</sup> | Giesy et al., 2000 |

<sup>a</sup> NOAEL: No Observable Adverse Effect Level

<sup>b</sup> NML: No mortality level

#### 4.2.3 Chronic Mammalian Toxicity to Glyphosate

Chronic effect levels of glyphosate (tested as an acid) were estimated from long-term (13-52 weeks) dietary studies in the rat, mouse, and dog models. In terms of subchronic and chronic toxicity in rodents, one of the more consistent effects of exposure to glyphosate is loss of body

weight. Toxicity varied significantly both within and across species. Across species, the NOAEL in mammals ranged from 30 mg a.e./kg/d to > 12,500 mg a.e./kg/diet. Within species, the rat showed the most extreme variation (NOAEL ranged from 30 mg a.e./kg/d to > 12,500 mg a.e./kg/diet), followed by the mouse (NOAEL ranged from 507 to 1,890 mg a.e./kg/d). Only one study using a dog model was reviewed and therefore variability cannot be assessed. A 3-generation reproduction study was conducted with male and female Sprague-Dawley rats which were administered 0, 3, 10, or 30 mg/kg/day of glyphosate continuously in the diet. The only effect observed was an increased incidence of focal tubular dilation of the kidney (both unilateral and bilateral combined) in the high-dose male F<sub>3b</sub> pups. Therefore, the NOEL for systemic and reproductive toxicity is 30 mg/kg/day (US EPA, 1993). A second reproductive study was conducted. In the 2-generation rat reproduction study, the offspring and parental NOAELs were 500 mg/kg/day based on decreased pup body weight during lactation (offspring) and soft stools, decreased body weight and food consumption (parents) at the LOAEL of 1500 mg/kg/day. The reproductive NOAEL was >1500 mg/kg/day. The focal tubular dilation of the kidneys was not observed at the 1500 mg/kg/day level in the subsequent 2-generation rat reproduction study. Therefore, the EPA concluded that the effect seen in the three generation study was a spurious rather than glyphosate-related effect. Therefore, the NOAELs for parental, reproductive or offspring toxicity were 30 mg/kg/day. The toxicity results are presented in table N-15.

**Table N-15. Chronic Mammalian Toxicity to Glyphosate**

| Study Type (%a.i.)     | Species | Results                          | Endpoint                                                                                                                                               | Reference                                 |
|------------------------|---------|----------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------|
| 13-wk, Dietary         | Rat     | NOAEL = 205 mg a.e./kg/d         | NOAEL                                                                                                                                                  | Giesy et al., 2000                        |

#### 4.2.4 Chronic Mammalian Toxicity to Glyphosate Herbicide Formulations

No studies were found addressing the chronic toxicity of commercial formulations of glyphosate to terrestrial mammals.

### 4.3 Terrestrial Invertebrate Toxicity

Several acute toxicity tests were conducted on terrestrial invertebrates for glyphosate and its formulations. No studies were found addressing the chronic toxicity of glyphosate and its commercial formulations on terrestrial invertebrates. The toxicity study results are discussed in sections 4.3.1 through 4.3.4.

#### 4.3.1 Acute Terrestrial Invertebrate Toxicity to Glyphosate

Acute toxicity in non-target arthropods was assessed using contact, oral, and dietary studies. The preferred US EPA test species for non-target arthropods is the honeybee. Studies may also use spiders, butterflies, or other terrestrial arthropods (USDA, 2003). All reviewed studies reported a LD<sub>50</sub> for glyphosate of > 100 µg/honeybee. No studies were reviewed that tested glyphosate as an acid or IPA salt. The study results are presented in table N-16 below.

**Table N-16. Acute Terrestrial Invertebrate Toxicity to Glyphosate**

| Study Type (%a.i.)           | Species  | Results                                             | Endpoint | Reference          |
|------------------------------|----------|-----------------------------------------------------|----------|--------------------|
| Acute, Diet                  | Honeybee | LD <sub>50</sub> = 100; 2-day; range not reported   | Death    | Giesy et al., 2000 |
| Acute, Contact               | Honeybee | LD <sub>50</sub> = > 100; 2-day; range not reported | Death    | Giesy et al., 2000 |
| Acute, Oral                  | Honeybee | LD <sub>50</sub> = > 100 µg/bee                     | Death    | US EPA, 1993       |
| Acute, Contact               | Honeybee | LD <sub>50</sub> = > 100 µg/bee                     | Death    | US EPA, 1993       |
| Acute, Oral (36% MON2139)    | Honeybee | LD <sub>50</sub> = > 100 µg/bee                     | Death    | US EPA, 1993       |
| Acute, Contact (36% MON2139) | Honeybee | LD <sub>50</sub> = > 100 µg/bee                     | Death    | US EPA, 1993       |

#### 4.3.2 Acute Terrestrial Invertebrate Toxicity to Glyphosate Herbicide Formulations

The formulations of glyphosate (Honcho® Herbicide, Honcho® Plus Herbicide, Roundup Original MAX® Herbicide, and Roundup WeatherMAX® Herbicide) produced LD<sub>50</sub> values between 100 and 326 µg/honeybee. Non-target arthropods appeared most sensitive to Roundup WeatherMAX® and least sensitive to Honcho® products. The study results are presented in table N-17 below.

**Table N-17. Acute Terrestrial Invertebrate Toxicity to Glyphosate Herbicide Formulations**

| Study Type (% a.i.)                                    | Species  | Results                         | Endpoint | Reference          |
|--------------------------------------------------------|----------|---------------------------------|----------|--------------------|
| Acute, Diet (Roundup)                                  | Honeybee | LD <sub>50</sub> = > 100 µg/bee | Death    | Giesy et al., 2000 |
| Acute, Contact (Roundup)                               | Honeybee | LD <sub>50</sub> = > 100 µg/bee | Death    | Giesy et al., 2000 |
| 48-hr, Oral (Roundup WeatherMAX® Herbicide)            | Honeybee | LD <sub>50</sub> > 238.8 µg/bee | Death    | Monsanto, 2005     |
| 48-hr, Contact (Roundup WeatherMAX® Herbicide)         | Honeybee | LD <sub>50</sub> > 250 µg/bee   | Death    | Monsanto, 2005     |
| 48-hr, Contact (Roundup Original MAX® Herbicide)       | Honeybee | LD <sub>50</sub> > 273 µg/bee   | Death    | Monsanto, 2006     |
| 48-hr, Oral toxicity (Roundup Original MAX® Herbicide) | Honeybee | LD <sub>50</sub> > 281 µg/bee   | Death    | Monsanto, 2006     |
| 48-hr, Oral/Contact (Honcho® Herbicide)                | Honeybee | LD <sub>50</sub> > 326 µg/bee   | Death    | Monsanto, 2007b    |
| 48-hr, Oral/Contact (Honcho® Plus Herbicide)           | Honeybee | LD <sub>50</sub> > 326 µg/bee   | Death    | Monsanto, 2007d    |

### 4.3.3 Chronic Terrestrial Invertebrate Toxicity to Glyphosate and Glyphosate Herbicide Formulations

No studies were found addressing the chronic toxicity of glyphosate and commercial formulations of glyphosate to terrestrial invertebrates.

## 4.4 Plant Toxicity

Several acute toxicity tests were conducted on plants for exposure to glyphosate, as well as were several chronic toxicity tests on glyphosate and its formulations. Glyphosate is a broad-spectrum herbicide and will affect many types of nontarget plants if applied to the foliage. Therefore, a detailed risk assessment on the impact of foliar application of glyphosate in the treated area was not conducted. No studies were found addressing the acute toxicity of commercial formulations of glyphosate to plants. The toxicity study results are discussed in sections 4.4.1 through 4.4.4.

### 4.4.1 Acute Plant Toxicity to Glyphosate

Glyphosate is estimated to be equally toxic to both terrestrial and aquatic plants (USDA, 2003). US EPA has evaluated glyphosate's toxicity to aquatic plants based on studies submitted for the registration of the chemical and additional studies are also available (USDA, 2003). Table N-18 highlights glyphosate's acute toxicity levels for 26 aquatic plant species. EC<sub>50</sub> values for glyphosate in algae are as low as 0.85 mg/L (USDA, 2003). Aquatic macrophyte sensitivity to glyphosate is similar to that of algae (USDA, 2003).

**Table N-18. Acute Non-Target Aquatic Plants Toxicity to Glyphosate**

| Study Type (% a.i.)          | Species                          | Result                                                                         | Endpoint             | Reference    |
|------------------------------|----------------------------------|--------------------------------------------------------------------------------|----------------------|--------------|
| Aquatic Plant Growth (96.6%) | <i>Selenastrum capricornutum</i> | EC <sub>50</sub> = 12.5 mg/L, 4-day                                            | Not reported         | US EPA, 1993 |
| Aquatic Plant Growth (96.6%) | <i>Navicula pelliculosa</i>      | EC <sub>50</sub> = 39.9 mg/L, 4-day                                            | Not reported         | US EPA, 1993 |
| Aquatic Plant Growth (96.6%) | <i>Skeletonema costatum</i>      | EC <sub>50</sub> = 0.85 mg/L, 4-day                                            | Not reported         | US EPA, 1993 |
| Aquatic Plant Growth (96.6%) | <i>Anabaena flosaquae</i>        | EC <sub>50</sub> = 11.7 mg/L, 4-day                                            | Not reported         | US EPA, 1993 |
| Aquatic Plant Growth (96.6%) | <i>Lemna gibba</i>               | EC <sub>50</sub> = 21.5 mg/L, 7-day                                            | Not reported         | US EPA, 1993 |
| Aquatic Plant Growth (96.6%) | <i>Chlorella fusca</i>           | EC <sub>50</sub> = 377 mg/L, 1 generation cycle (24-hours), range not reported | Not reported         | USDA, 2003   |
| Aquatic Plant Growth (96.6%) | <i>Chlorella pyrenoidosa</i>     | EC <sub>50</sub> = 590 mg/L, 4-day                                             | Not reported         | USDA, 2003   |
| Aquatic Plant Growth (96.6%) | <i>Chlorococcum hypnosporum</i>  | EC <sub>50</sub> = 68 mg/L, 4-day                                              | Not reported         | USDA, 2003   |
| Aquatic Plant Growth (96.6%) | <i>Zygnema cylindricum</i>       | EC <sub>50</sub> = 88 mg/L, 4-day                                              | Not reported         | USDA, 2003   |
| Aquatic Plant Growth (96.6%) | <i>Anabaena flosaquae</i>        | EC <sub>50</sub> = 304 mg/L, 4-day                                             | Not reported         | USDA, 2003   |
| Aquatic Plant Growth         | <i>Cyclotella</i>                | 73% inhibition at 2.8                                                          | Inhibition of carbon | USDA, 2003   |

a.e.= glyphosate acid equivalent

<sup>a</sup> Negative values indicate stimulation

<sup>b</sup> Derived from an acute EC<sub>50</sub>/chronic NOEC ratio of 20

#### 4.4.2 Acute Plant Toxicity to Glyphosate Herbicide Formulations

No studies were found addressing the acute toxicity of commercial formulations of glyphosate to plants.

#### 4.4.3 Acute Plant Toxicity to AMPA

Table N-19 shows the acute plant toxicity of AMPA. The EC<sub>50</sub> was established to be 90 mg/L while the NOEC was 7.9 mg/L.

**Table N-19. Aquatic Plants Toxicity to AMPA**

| Study Type           | Species                        | Result                                         | Endpoint     | Reference          |
|----------------------|--------------------------------|------------------------------------------------|--------------|--------------------|
| 3-day Acute Toxicity | <i>Scenedesmus subspicatus</i> | NOEC = 7.9 mg/L;<br>EC <sub>50</sub> = 90 mg/L | Not reported | Giesy et al., 2000 |

#### 4.4.4 Chronic Plant Toxicity to Glyphosate

Table N-20 shows the chronic toxicity of glyphosate on three non-target aquatic plant species. A Tier II terrestrial seedling emergence study indicated <25% effects at a rate of 4.0 lbs ai/A (US EPA, 2006AA). In a Tier II vegetative vigor test on terrestrial plants, found that oil rape seed was the most sensitive dicot species, with phytotoxicity as the most sensitive effect; the EC<sub>25</sub> was 0.074 lb ai/A and NOAEL of 0.038 lb ai/A. The most sensitive monocot species was winter wheat, with dry weight as the most sensitive effect, the EC<sub>25</sub> was 0.159 lb ai/A and NOAEL of 0.049 lb ai/A (US EPA, 2006AA). EC<sub>50</sub> values for glyphosate are as low as 1.6 mg a.e./L (USDA, 2003).

In concentration ranges of 0.002 mg/L to 0.3 mg/L, glyphosate is used as a phosphorus nutrient source for some algae since glyphosate stimulates algal growth at these concentrations (USDA, 2003).

**Table N-20. Chronic Non-Target Aquatic Plants Toxicity to Glyphosate**

| Study Type | Species             | Result                                                                                          | Endpoint                                        | Reference          |
|------------|---------------------|-------------------------------------------------------------------------------------------------|-------------------------------------------------|--------------------|

| Chronic    | <i>Lemna gibba</i>  | EC <sub>50</sub> = 25.5 mg a.e./L<br>NOEC = 16.6 mg/L; 14-day,<br>no range reported             | Growth Inhibition                               | Giesy et al., 2000 |

<sup>b</sup> Derived from an acute EC<sub>50</sub>/chronic NOEC ratio of 20

### 4.5 Soil Invertebrates and Microorganisms Toxicity

The results of toxicity studies in soil invertebrates and microorganisms from exposure to glyphosate and its formulations are discussed in sections 4.5.1 through 4.5.4 below.

#### 4.5.1 Soil Invertebrates Toxicity to Glyphosate

The results of glyphosate toxicity studies in invertebrates are provided in table N-21. The sensitivity of the earthworm to glyphosate was tested in two 14-day dietary studies using glyphosate IPA salt. The NOEC was determined to be 118.7 mg/kg soil in one study, and the No mortality level was found to be 3,750 mg/kg soil in a second study.

**Table N-21. Soil Invertebrates Toxicity to Glyphosate**

| Study Type (% a.i.) | Species   | Results                 | Endpoint          | Reference          |
|---------------------|-----------|-------------------------|-------------------|--------------------|
| 14-day, Dietary     | Earthworm | NOEC = 118.7 mg/kg soil | NOEC <sup>a</sup> | Giesy et al., 2000 |
| 14-day, Dietary     | Earthworm | NML = 3750 mg/kg soil   | NML <sup>b</sup>  | Giesy et al., 2000 |

<sup>a</sup> NOEC: No Observed Effect Concentration

<sup>b</sup> NML: No Mortality Level

#### 4.5.2 Soil Invertebrates Toxicity to Glyphosate Herbicide Formulations

The sensitivity of the earthworm to Honcho® Herbicide, Honcho® Plus Herbicide, Roundup Original MAX® Herbicide, and Roundup WeatherMAX® was tested in 14-day dietary and acute toxicity studies. The acute toxicity values are provided in table N-22. The NOEC for earthworms was determined to be 500 mg/kg soil in one study, and the NML was found to be 5,000 mg/kg soil in a second study.

**Table N-22. Soil Invertebrates Toxicity to Glyphosate Herbicide Formulations**

| Study Type (% a.i.)                                      | Species   | Results                                  | Endpoint | Reference          |
|----------------------------------------------------------|-----------|------------------------------------------|----------|--------------------|
| 14-day, Dietary (Roundup)                                | Earthworm | NOEC = 500 mg/kg soil                    | NOEC     | Giesy et al., 2000 |
| 14-day, Acute toxicity (Honcho® Herbicide)               | Earthworm | LC <sub>50</sub> > 5,000 mg/kg dry soil  | Death    | Monsanto, 2007b    |
| 14-day, Acute toxicity (Honcho® Plus Herbicide)          | Earthworm | LC <sub>50</sub> > 5,000 mg/kg dry soil  | Death    | Monsanto, 2007d    |
| 14-day, Dietary (Roundup)                                | Earthworm | NML = 5000 mg/kg soil                    | NML      | Giesy et al., 2000 |
| 14-day, Acute toxicity (Roundup Original MAX® Herbicide) | Earthworm | LC <sub>50</sub> > 10,000 mg/kg dry soil | Death    | Monsanto, 2006     |
| 14-day, Acute toxicity (Roundup WeatherMAX® Herbicide)   | Earthworm | LC <sub>50</sub> > 10,000 mg/kg dry soil | Death    | Monsanto, 2005     |

#### 4.5.3 Soil Microorganism Toxicity to Glyphosate

Soil microbes readily metabolize glyphosate into AMPA and other metabolites (USDA, 2003). Microorganisms produce aromatic amino acids through the shikimate pathway, similar to plants. Since glyphosate inhibits this pathway, it could be expected that glyphosate would be toxic to microorganisms. However, field studies show that glyphosate has little effect on soil microorganisms, and, in some cases, field studies have shown an increase in microbial activity (USDA, 2003).

Studies tested the effects of glyphosate and glyphosate formulations on soil microbe's ability for nitrification, denitrification, dehydrogenase activity, nitrogen fixation, urea hydrolysis,

immobilization of ammonium, ammonification, and degradation of cellulose, starch, protein, and leaf litter. *In vitro* studies were excluded from this report due to challenges associated with extrapolating the results of *in vitro* environments to natural soil ecosystems.

The results of chronic glyphosate acid toxicity studies in soil microbes are provided in table N-23. Microbial activities including degradation of leaf litter, cellulose, starch, and protein showed the least sensitivity to glyphosate, while ammonification, denitrification, nitrification, and nitrogen fixation were more sensitive. However, one 3-day nitrification study produced no observable adverse effects up to a concentration of 76.7 mg a.e./kg. Alfalfa is a legume that forms a symbiotic relationship with the nitrogen-fixing bacterium, *Sinorhizobium meliloti*. The result is the conversion of atmospheric nitrogen to fixed nitrogen in the soil, resulting in a net increase in available nitrogen to the soil. GT alfalfa does not alter the symbiotic association with *S. meliloti* and does not negatively affect the availability of nitrogen in the soil.

**Table N-23. Soil Microorganism Toxicity to Glyphosate**

| Study Type (% a.i.)                               | Species            | Result <sup>a</sup>       | Endpoint <sup>b</sup> | Reference          |
|---------------------------------------------------|--------------------|---------------------------|-----------------------|--------------------|
| 7-day, Ammonification                             | Soil Microorganism | NOAEC = 10 mg a.e./kg     | NOAEC                 | Giesy et al., 2000 |
| 7, 14-day, Denitrification                        | Soil Microorganism | NOAEC = 10 mg a.e./kg     | NOAEC                 | Giesy et al., 2000 |
| 14-day, Nitrification                             | Soil Microorganism | NOAEC = < 10 mg a.e./kg   | NOAEC                 | Giesy et al., 2000 |
| 21-day, Nitrification                             | Soil Microorganism | NOAEC = 10 mg a.e./kg     | NOAEC                 | Giesy et al., 2000 |
| 3-day, Nitrification                              | Soil Microorganism | NOAEC = < 76.7 mg a.e./kg | NOAEC                 | Giesy et al., 2000 |
| 7-day, Nitrogen fixation                          | Soil Microorganism | NOAEC = 12.7 mg a.e./kg   | NOAEC                 | Giesy et al., 2000 |
| 84-day, Degradation of cellulose, starch, protein | Soil Microorganism | NOAEC = 25 mg a.e./kg     | NOAEC                 | Giesy et al., 2000 |
| 84-day, Degradation of leaf litter                | Soil Microorganism | NOAEC = 25 mg a.e./kg     | NOAEC                 | Giesy et al., 2000 |

<sup>a</sup> a.e., glyphosate acid equivalents

<sup>b</sup> NOAEC unless specified. Effects may have been observed at higher levels, but they were not judged to be adverse (e.g., stimulatory effects).

#### 4.5.4 Soil Microorganism Toxicity to Glyphosate Herbicide Formulations

The results of chronic toxicity studies of Roundup in soil microbes are provided in table N-24. The No Observable Adverse Effect Concentration (NOAEC) endpoint was determined for various microbial activities, including dehydrogenase activity, immobilization of ammonium, nitrification, nitrogen fixation, urea hydrolysis, and nitrogen and carbon transformation. Microbial response to Roundup varied significantly. For example, the NOAEC for microbial nitrification ranged from 5 mg a.e./kg to 230 mg a.e./kg, and the NOAEC for urea hydrolysis ranged from 5 mg a.e./kg (1-day study) to 50 mg a.e./kg (42-day study).

**Table N-24. Soil Microorganism Toxicity to Glyphosate Herbicide Formulations**

| Study Type (% a.i)                                                           | Species            | Results                 | Endpoint <sup>a</sup>                                              | Reference          |

<sup>a</sup> NOAEC unless specified. Effects may have been observed at higher levels, but they were not judged to be adverse (e.g., stimulatory effects).

## 4.6 Amphibian Toxicity

The results of toxicity studies in amphibians from exposure to glyphosate and its formulations are discussed in sections 4.6.1 through 4.6.2 below.

### 4.6.1 Amphibian Toxicity to Glyphosate

Amphibians use a wide range of aquatic habitats for their breeding sites and could be exposed to glyphosate in surface water. This would most likely occur as a result of heavy rainfall after a recent application and subsequent dissipation into stream sediment (Lajmanovich, 2003). Acute toxicity of glyphosate in amphibians was assessed using 2-day and 4-day acute toxicity studies in tadpoles. Amphibians showed greater sensitivity to glyphosate tested as an acid; LC<sub>50</sub>s for

amphibians ranged from 78 to 121 mg a.e./L for glyphosate tested as acid and 343-466 mg a.e./L for glyphosate tested as IPA salt. The study results are presented in table N-25 below.

**Table N-25. Amphibian Toxicity to Glyphosate**

| Study Type (%a.i.)                   | Species                                         | Results                                                    | Endpoint | Reference          |
|--------------------------------------|-------------------------------------------------|------------------------------------------------------------|----------|--------------------|

| 4-day, Acute toxicity                | Tadpole ( <i>L. moorei</i> )                    | LC <sub>50</sub> = 111 mg a.e./L                           | Death    | Giesy et al., 2000 |

#### 4.6.2 Amphibian Toxicity to Glyphosate Herbicide Formulations

Acute toxicity of Roundup in amphibians was assessed using 2-day and 4-day acute toxicity studies in tadpoles. Table N-26 provides acute toxicity LC<sub>50</sub> values for the five tadpole species tested (*C. insignifera*, *H. eyrei*, *L. dorsalis*, *L. moorei*, and *X. laevis*). Amphibians' sensitivity to Roundup varied significantly, both within and across species. LC<sub>50</sub>s for amphibians ranged from 8.1 mg Roundup glyphosate equivalent (a.e.) (RU)/L for *L. moorei* and 175 mg RU/L for *H. eyrei*. In general, adult tadpoles demonstrated higher tolerances to Roundup than juveniles, with the exception of one study performed with *C. insignifera* newly emerged tadpoles (LC<sub>50</sub> 144 mg RU/L).

Amphibians exhibited greater sensitivity to Roundup formulations (LC<sub>50</sub> 8.1 to 175 mg RU/L) than to glyphosate tested as an acid or IPA salt (LC<sub>50</sub> 78 to 466 mg a.e./L). This could be due to the surfactant (POEA) used in agricultural formulations, which has been found to be more toxic to amphibians and other aquatic animals than the herbicide itself (Lajmanovich, 2003). Some researchers have suggested that Roundup (in combination with POEA) could cause extremely high rates of mortality to amphibians that could lead to eventual population declines (Relyea, 2005).

**Table N-26. Amphibian Toxicity to Glyphosate Herbicide Formulations**

| Study Type (% a.i.)             | Species                                         | Results                                                | Endpoint | Reference          |
|---------------------------------|-------------------------------------------------|--------------------------------------------------------|----------|--------------------|
| 2-day, Acute toxicity (Roundup) | Tadpole ( <i>C. insignifera</i> )               | LC <sub>50</sub> = 10 mg RU/L                          | Death    | Giesy et al., 2000 |
| 2-day, Acute toxicity (Roundup) | Tadpole ( <i>C. insignifera</i> )               | LC <sub>50</sub> = < 54.9 mg RU/L                      | Death    | Giesy et al., 2000 |
| 4-day, Acute toxicity (Roundup) | Adult tadpole ( <i>C. insignifera</i> )         | LC <sub>50</sub> = 96.8 mg RU/L<br>NOEC = 54 mg RU/L   | Death    | Giesy et al., 2000 |
| 2-day, Acute toxicity (Roundup) | Adult tadpole ( <i>C. insignifera</i> )         | LC <sub>50</sub> = 137 mg RU/L                         | Death    | Giesy et al., 2000 |
| 2-day, Acute toxicity (Roundup) | Newly emerged tadpole ( <i>C. insignifera</i> ) | LC <sub>50</sub> = 144 mg RU/L                         | Death    | Giesy et al., 2000 |
| 2-day, Acute toxicity (Roundup) | Tadpole ( <i>H. eyrei</i> )                     | LC <sub>50</sub> = 175 mg RU/L                         | Death    | Giesy et al., 2000 |
| 2-day, Acute toxicity (Roundup) | Tadpole ( <i>L. dorsalis</i> )                  | LC <sub>50</sub> = 8.3 mg RU/L                         | Death    | Giesy et al., 2000 |
| 2-day, Acute toxicity (Roundup) | Tadpole ( <i>L. moorei</i> )                    | LC <sub>50</sub> = 8.1 mg RU/L<br>NOEC = 1.6 mg RU/L   | Death    | Giesy et al., 2000 |
| 4-day, Acute toxicity (Roundup) | Tadpole ( <i>L. moorei</i> )                    | LC <sub>50</sub> = 18.7 mg RU/L<br>NOEC = 55 mg RU/L   | Death    | Giesy et al., 2000 |
| 2-day, Acute toxicity (Roundup) | Tadpole ( <i>L. moorei</i> )                    | LC <sub>50</sub> = 32.2 mg RU/L                        | Death    | Giesy et al., 2000 |
| 4-day, Acute toxicity (Roundup) | Adult tadpole ( <i>L. moorei</i> )              | LC <sub>50</sub> = > 165 mg RU/L<br>NOEC = 165 mg RU/L | Death    | Giesy et al., 2000 |
| 4-day, Acute toxicity (Roundup) | <i>Xenopus laevis</i> , embryo                  | LC <sub>50</sub> = 72 mg RU/L                          | Death    | Giesy et al., 2000 |

#### 4.6.3 California Red Legged Frog Toxicity to Glyphosate, Glyphosate Salts, and Glyphosate Formulations

In 2008, the EPA published a risk assessment to determine the effects of glyphosate, its salts, and glyphosate herbicide formulations on the California Red Legged Frog (CRLF)(<http://www.epa.gov/espp/litstatus/effects/redleg-frog/glyphosate/determination.pdf>). Use of glyphosate on alfalfa was one of the uses assessed in the risk assessment. We are incorporating this risk assessment by reference. From the EPA risk assessment:

“There are no direct effects on the aquatic-phase CRLF for any of the terrestrial or aquatic uses. The terrestrial-phase CRLF eating broadleaf plants, small insects and small herbivorous mammals on a dietary-basis may be at risk to direct effects following chronic exposure to glyphosate at application rates of 7.5 lb a.e./A [acre] and above (forestry, areas with impervious surfaces and rights of way). In addition, terrestrial phase amphibians may be at risk following acute exposure to one particular formulation (Registration No. 524-424), at application rates of 1.1 lbs formulation/A and above (ornamental lawns and turf and industrial outdoor uses). Indirect effects to the aquatic-phase CRLF, based on reduction in the prey base may occur with aquatic nonvascular

plants with aquatic weed management uses at an application rate of 3.75 lb a.e./A. Indirect effects to the terrestrial-phase CRLF, based on reduction in the prey base may occur with small insects at any registered rate, large insects at an application rate of 7.95 lb a.e./A (forestry uses), terrestrial phase amphibians following chronic exposure at application rates of 7.5 lb a.e./A and above and following acute exposure to one formulation at application rates of 1.1 lbs formulation/A and above and mammals following chronic exposure at application rates of 3.84 lbs a.e./A and above (i.e., many crops, forestry, rights of way and areas with impervious surfaces).

Indirect effects to both the aquatic- and terrestrial-phase CRLF, based on habitat effects may occur with aquatic non-vascular plants following aquatic weed management use and with aquatic emergent plants and terrestrial plants exposed via spray drift with aerial application at rates of 3.75 lbs /A and above and with ground applications at a rate of 7.95 lbs/A.”

Note that in all cases, the application rate is more than double the maximum single use (ground or aerial) application for GT alfalfa (1.55 lbs a.e./acre; ). The formulation that may have indirect toxic effects for CRLF is a formulation for ornamental planting and lawn/turf grasses, not for GT alfalfa uses.

#### 4.7 Aquatic Invertebrate Toxicity

Several acute and chronic toxicity tests were conducted on aquatic invertebrates for exposure to glyphosate and its formulations. A study was also conducted on the toxic effects of the metabolite AMPA on aquatic invertebrates. The toxicity study results are discussed in sections 4.7.1 through 4.7.4.

##### 4.7.1 Acute Aquatic Invertebrate Toxicity to Glyphosate

The acute toxicity of glyphosate to aquatic invertebrates is summarized in table N-27. The most sensitive species to glyphosate (96.7% a.i.) was *Chironomus plumosus* with a 48-hour EC<sub>50</sub> of 55 ppm (US EPA, 1993). The 48-hour EC<sub>50</sub> for *Daphnia magna* ranged from 780 mg/L (tested as an acid) to 930 mg/L (tested as the IPA salt), with a NOEC value of 560 mg/L (Giesy et al., 2000).

**Table N-27. Acute Aquatic Invertebrate Toxicity to Glyphosate**

| <b>Study Type (% a.i.)</b> | <b>Species</b>                  | <b>Result</b>                                                                            | <b>Endpoint</b> | <b>Reference</b>                |
|----------------------------|---------------------------------|------------------------------------------------------------------------------------------|-----------------|---------------------------------|
| Acute (96.7%)              | <i>Chironomus plumosus</i>      | LC <sub>50</sub> (95% CL) = 55 ppm (31-97), 48-hour                                      | Death           | US EPA, 1993                    |

#### 4.7.2 Acute Aquatic Invertebrate Toxicity to Glyphosate Herbicide Formulations

The acute toxicity of glyphosate formulations to aquatic invertebrates is summarized in table N-28. The most sensitive species to glyphosate formulations was *Daphnia magna* with a 48-hour EC<sub>50</sub> of 3.0 ppm (USDA, 2003). The 48-hour EC<sub>50</sub> for *Daphnia magna* ranged from 3.0 ppm to 160 mg/L (USDA, 2003; Monsanto, 2005, 2006, 2007b, 2007d). As evidenced by this data, glyphosate formulations are several orders of magnitude more toxic to *Daphnia magna* than technical glyphosate. The 48-hour EC<sub>50</sub> for *Chironomus plumosus* was 58.1 ppm (Giesy et al., 2000). Toxicity values (96-hour EC<sub>50</sub> or LC<sub>50</sub>) for *Gammarus pseudolimnaeus* ranged from 42 mg/L to 200 mg/L, with a NOEC value of 4.4 mg/L (Giesy et al., 2000).

**Table N-28. Acute Aquatic Invertebrate Toxicity to Glyphosate Herbicide Formulation**

| Study Type             | Formulation           | Species                                               | Result                                                                             | Endpoint     | Reference          |
|------------------------|-----------------------|-------------------------------------------------------|------------------------------------------------------------------------------------|--------------|--------------------|
| Acute Toxicity         | Roundup               | Fourth instar <i>Anopheles quadrimaculatus</i> larvae | LC <sub>50</sub> (95% CL) = 673.43 ppm (572.57-770.17), 24-hour                    | Death        | USDA, 2003         |
| Acute Toxicity         | Roundup               | <i>Chironomus plumosus</i>                            | Toxicity Value <sup>a</sup> = 58.1 mg/L <sup>b</sup> , 48-hour, range not reported | Not reported | Giesy et al., 2000 |
| Acute Toxicity         | Roundup               | <i>Ceriodaphnia dubia</i>                             | LC <sub>50</sub> (95% CL) = 5.39 mg/L (4.81-6.05), 48-hour                         | Death        | Tsui and Chu, 2003 |
| Acute Toxicity         | Roundup               | Fourth instar <i>Culex salinarius</i> larvae          | LC <sub>50</sub> (95% CL) = 1563.69 ppm (1262.00-2214.54), 24-hour                 | Death        | USDA, 2003         |
| Acute Toxicity         | Roundup               | <i>Daphnia magna</i>                                  | EC <sub>50</sub> (95% CL) = 3.0 ppm (2.6-3.4), 48-hour                             | Not reported | USDA, 2003         |
| Acute Toxicity, Static | Roundup Original MAX® | <i>Daphnia magna</i>                                  | EC <sub>50</sub> = 8.0 mg/L <sup>c</sup> , 48-hour                                 | Not reported | Monsanto, 2006     |
| Acute Toxicity, Static | Roundup WeatherMAX®   | <i>Daphnia magna</i>                                  | EC <sub>50</sub> = 8.0 mg/L <sup>c</sup> , 48-hour                                 | Not reported | Monsanto, 2005     |
| Acute Toxicity, Static | Roundup UltraMAX® II  | <i>Daphnia magna</i>                                  | EC <sub>50</sub> = 8.0 mg/L <sup>c</sup> , 48-hour                                 | Not reported | Monsanto, 2003     |
| Acute Toxicity         | Roundup               | <i>Daphnia magna</i>                                  | EC <sub>50</sub> = 9.7 mg/L <sup>b</sup> , 48-hour<br>NOEC = 1.9 mg/L <sup>d</sup> | Not reported | Giesy et al., 2000 |
| Acute Toxicity, Static | Honcho®               | <i>Daphnia magna</i>                                  | EC <sub>50</sub> = 11.0 mg/L <sup>c</sup> , 48-hour                                | Not reported | Monsanto, 2007b    |
| Acute Toxicity         | Roundup               | <i>Daphnia magna</i>                                  | Toxicity Value <sup>a</sup> = 12.9 mg/L <sup>b</sup> ; 48-hour<br>NOEC = 4.6 mg/L  | Not reported | Giesy et al., 2000 |
| Acute Toxicity         | Roundup               | <i>Daphnia magna</i>                                  | Toxicity Value <sup>a</sup> = 24 mg/L; 48-hour<br>NOEC = 7.8 mg/L                  | Not reported | Giesy et al., 2000 |
| Acute Toxicity, Static | Honcho® Plus          | <i>Daphnia magna</i>                                  | EC <sub>50</sub> = 160 mg/L, 48-hour                                               | Not reported | Monsanto, 2007d    |

| Study Type     | Formulation | Species                                          | Result                                                                                                      | Endpoint     | Reference          |
|----------------|-------------|--------------------------------------------------|-------------------------------------------------------------------------------------------------------------|--------------|--------------------|
| Acute Toxicity | Roundup     | <i>Daphnia pulex</i>                             | EC <sub>50</sub> (95% CL) = 3.2 ppm (3.0-3.4), 48-hour                                                      | Not reported | USDA, 2003         |
| Acute Toxicity | Roundup     | <i>Daphnia pulex</i>                             | EC <sub>50</sub> (95% CL) = 7.9 ppm (7.2-8.6), 48-hour                                                      | Not reported | USDA, 2003         |
| Acute Toxicity | Roundup     | <i>Daphnia pulex</i>                             | Toxicity Value <sup>a</sup> = 19 mg/L, 48-hour                                                              | Not reported | Giesy et al., 2000 |
| Acute Toxicity | Roundup     | <i>Daphnia pulex</i>                             | Toxicity Value <sup>a</sup> = 25.5 mg/L, 96-hour                                                            | Not reported | Giesy et al., 2000 |

<sup>c</sup> Values are derived from a similar formulation

<sup>d</sup> Derived from an acute EC<sub>50</sub>/acute NOEC ratio of 5

#### 4.7.3 Acute Aquatic Invertebrate Toxicity to AMPA

The acute toxicity of AMPA to the freshwater flea – *Daphnia magna* is shown below in table N-29. The NOEC was 320 mg AMPA/L while the EC<sub>50</sub>/LC<sub>50</sub> was observed to be 690 mg/L.

**Table N-29. Acute Aquatic Invertebrate Toxicity to AMPA**

| Study Type (% a.i.) | Species              | Result                                                 | Endpoint     | References         |
|---------------------|----------------------|--------------------------------------------------------|--------------|--------------------|
| 2 day – Acute       | <i>Daphnia magna</i> | NOEC = 320 mg AMPA/L; LC <sub>50</sub> = 690 mg AMPA/L | Not reported | Giesy et al., 2000 |

#### 4.7.4 Chronic Aquatic Invertebrate Toxicity to Glyphosate

Several studies are available addressing the chronic toxicity of glyphosate to freshwater invertebrates (table N-30). A MATC of between 50 and 96 mg/L was determined for *Daphnia magna* in a flow-through study with glyphosate (99.7% a.i.) (US EPA, 1993). A flow-through study reported a 21-day NOEC of 100 mg/L (Giesy et al., 2000). A 4-week study in *Pseudosuccinea columella* observed increased protein concentrations of snails reared in 1.0 mg/L glyphosate compared to those reared in 0.1 mg/L (USDA, 2003). Another 4-week developmental study in *Pseudosuccinea columella* with glyphosate (93% a.i.) observed an increased quantity of free amino acid pool (USDA, 2003).

**Table N-30. Chronic Aquatic Invertebrate Toxicity to Glyphosate**

| Study Type (% a.i.)           | Species                         | Result                                                                                                                                                  | Endpoint                      | References         |
|-------------------------------|---------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------|--------------------|
| Chronic, flow-through (99.7%) | <i>Daphnia magna</i>            | MATC = > 50 - <96 mg/L, time frame exposure time not reported                                                                                           | Reduced reproductive capacity | US EPA, 1993       |
|                               | <i>Pseudosuccinea columella</i> | Increased protein concentration of snails reared in 1.0 mg/L compared to those reared in 0.1 mg/L; exact mechanism for response not determined; 4 weeks | Biochemical alteration        | USDA, 2003         |
| Developmental (93%)           | <i>Pseudosuccinea columella</i> | Increased quantity of free amino acid pool; 4 weeks                                                                                                     | Not reported                  | USDA, 2003         |
| <i>Tested as acid:</i>        |                                 |                                                                                                                                                         |                               |                    |
| Chronic, flow-through         | <i>Daphnia magna</i>            | NOEC = 50 mg a.e./L, 21-day, range not reported                                                                                                         | Not reported                  | Giesy et al., 2000 |
| Chronic, static               | <i>Daphnia magna</i>            | NOEC = 100 mg a.e./L, 21-day, range not reported                                                                                                        | Not reported                  | Giesy et al., 2000 |

#### 4.7.5 Chronic Aquatic Invertebrate Toxicity to Glyphosate Herbicide Formulations

The chronic toxicity of glyphosate formulations to aquatic invertebrates is summarized in table N-31. A 21-day study identified a NOEC of 3.2 mg/L for *Daphnia magna* (Giesy, et al., 2000). In accordance with acute toxicity observations, formulations of glyphosate were more toxic to *Daphnia magna* than technical glyphosate. A chronic toxicity study in *tubifex tubifex* identified a NOEC of greater than 89 mg/L (Giesy, et al., 2000).

**Table N-31. Chronic Aquatic Invertebrate Toxicity to Glyphosate Herbicide Formulation**

| Study Type       | Formulation | Species                | Result                  | Reference           |
|------------------|-------------|------------------------|-------------------------|---------------------|
| Chronic toxicity | Roundup     | <i>Daphnia magna</i>   | NOEC= 3.2 mg/L, 21 days | Giesy, et al., 2000 |
| Chronic toxicity | Roundup     | <i>Tubifex tubifex</i> | NOEC= >89 mg/L          | Giesy, et al., 2000 |

## 4.8 Fish Toxicity

Several acute and chronic toxicity tests were conducted on fish for exposure to glyphosate and its formulations. The toxicity study results are discussed in sections 4.8.1 through 4.8.5.

### 4.8.1 Acute Fish Toxicity to Glyphosate

A large number of studies have been performed in a variety of species of fish to determine the acute toxicity of glyphosate. The acute toxicity of glyphosate to freshwater fish is summarized in table N-32. Studies conducted on saltwater/estuarine fish were not reported. The most sensitive species to glyphosate is rainbow trout (fry), with a 96-hour LC<sub>50</sub> of 7.9 parts per million (ppm) (USDA, 2003). The 96-hour LC<sub>50</sub> of glyphosate to rainbow trout ranges from 7.9 ppm glyphosate (percent active ingredient [a.i.] unknown) to 25,657 mg/L glyphosate (38% a.i.) (USDA, 2003). This large range is most likely indicative of different study conditions. Sockeye salmon was observed to have an 96-hour LC<sub>50</sub> ranging from 8.1 ppm (fingerling) to 8.7 ppm (fry), and Coho salmon was observed to have an 96-hour LC<sub>50</sub> ranging from 12.8 ppm (fry) to 36 mg/L (glyphosate tested as an acid) (USDA, 2003).

For bluegill sunfish, a 96-hour Toxic Limit (TL)<sub>50</sub> of 24 ppm was reported for a dynamic study with glyphosate (96.5% a.i.) (USDA, 2003). Reported 96-hour LC<sub>50</sub> values ranged from 120 ppm to >1000 mg/L (tested as IPA salt) (USDA, 2003; Giesy et al., 2000). The 96-hour LC<sub>50</sub> value for channel catfish was 130 mg/L (tested as IPA salt) (Giesy et al., 2000). The 96-hour LC<sub>50</sub> for fathead minnow ranged from 84.9 mg/L (87.3% a.i.) to > 648 mg/L (tested as the IPA salt) (US EPA, 1993; Giesy et al., 2000). Salmonids are more sensitive to glyphosate than other species of fish.

**Table N-32. Acute Freshwater Fish Toxicity to Glyphosate**

| Study Type<br>(% a.i. if provided) | Species              | Result                                                    | Endpoint     | Reference               |
|------------------------------------|----------------------|-----------------------------------------------------------|--------------|-------------------------|
| Acute, Static                      | Rainbow Trout (fry)  | LC <sub>50</sub> = 7.8 ppm, 96-hour, range not reported   | Death        | USDA, 2003              |
| Acute, Static                      | Sockeye (fingerling) | LC <sub>50</sub> = 8.1 ppm, 96-hour, range not reported   | Death        | USDA, 2003              |
| Acute, Static                      | Sockeye (fingerling) | LC <sub>50</sub> = 8.4 ppm, 96-hour, range not reported   | Death        | USDA, 2003              |
| Acute, Static                      | Rainbow Trout (fry)  | LC <sub>50</sub> = 8.5 ppm, 96-hour, range not reported   | Death        | USDA, 2003              |

<sup>a</sup> Values for soft (creek) and hard (lake) water, respectively

<sup>b</sup> Linden E. et al. (1979) as cited in USDA, 2003 and Bionomics (1973c) as cited in Giesy et al., 2000 are believed to reference identical studies, but this can not be confirmed with available data. Therefore, both studies are listed.

<sup>c</sup> Monsanto Co. (1982a) as cited in USDA, 2003 and HRC (1977) as cited in Giesy et al., 2000 are believed to reference identical studies, but this can not be confirmed with available data. Therefore, both studies are listed.

#### 4.8.2 Acute Fish Toxicity to Glyphosate Herbicide Formulations

Many studies have also been performed in a variety of species of fish to determine the acute toxicity of glyphosate formulations. This ecotoxicity risk assessment was limited to glyphosate formulations suggested for use on GT alfalfa. The acute toxicity of glyphosate to freshwater fish is summarized in table N-33. Studies conducted on saltwater fish were not reported.

In general, the glyphosate formulations were more toxic to fish than technical glyphosate. The most sensitive species to the formulations considered was rainbow trout with an 96-hour LC<sub>50</sub> of 3.13 mg/L when treated with formulations similar to Roundup UltraMAX II® and Roundup WeatherMAX® (Monsanto, 2004 and 2005). Comparatively, the 96-hour LC<sub>50</sub> for rainbow trout treated with glyphosate was 7.9 ppm (which equates to 7.9 mg/L). The 96-hour LC<sub>50</sub> for rainbow trout treated with glyphosate formulations ranged from 3.13 mg/L to 52 mg/L (Monsanto, 2005, 2006, 2007b, 2007d; Giesy et al., 2000). Interestingly, salmon species were less sensitive to glyphosate formulations than to glyphosate. When treated with glyphosate formulations, sockeye salmon was observed to have an 96-hour LC<sub>50</sub> of 26.7 mg/L, and Coho salmon was observed to have an 96-hour LC<sub>50</sub> ranging from 13 ppm mg/L to 42 mg/L (Giesy et al., 2000).

For bluegill sunfish, reported 96-hour LC<sub>50</sub> values ranged from 5.2 mg/L to 34 mg/L (Monsanto, 2005, 2006, 2007b, 2007d; Giesy et al., 2000). The 96-hour LC<sub>50</sub> value for channel catfish ranged from 10.6 mg/L (fry) to 42 mg/L (adult) (Giesy et al., 2000). The 96-hour LC<sub>50</sub> for fathead minnow ranged from 7.4 mg/L to 23 mg/L. In bluegill sunfish, channel catfish, and fathead minnow, formulations of glyphosate are much more toxic than technical grade glyphosate (Giesy et al., 2000). The increased toxicity is due to the presence of a surfactant in glyphosate formulations.

**Table N-33. Acute Freshwater Fish Toxicity to Glyphosate Herbicide Formulation**

| Study Type                   | Formulation           | Species                   | Result                                                                              | Endpoint | Reference          |

| Acute Toxicity         | Roundup      | Coho Salmon                   | LC <sub>50</sub> = 27 mg/L, 13 mg/L <sup>c</sup> , 96-hour                         | Death    | Giesy et al., 2000 |
| Acute Toxicity         | Roundup      | Rainbow Trout                 | LC <sub>50</sub> = 27 mg/L, 96-hour<br>NOEC = 6.75 mg/L                            | Death    | Giesy et al., 2000 |
| Acute Toxicity         | Roundup      | Rainbow Trout                 | LC <sub>50</sub> = 27 mg/L <sup>b</sup> , 96-hour<br>NOEC = 21.4 mg/L <sup>b</sup> | Death    | Giesy et al., 2000 |
| Acute Toxicity         | Roundup      | Pink Salmon                   | LC <sub>50</sub> = 31 mg/L, 14 mg/L <sup>c</sup> , 96-hour                         | Death    | Giesy et al., 2000 |
| Acute Toxicity         | Roundup      | Rainbow Trout                 | LC <sub>50</sub> = 33.6 mg/L <sup>b</sup> , 96-hour                                | Death    | Giesy et al., 2000 |
| Acute Toxicity         | Roundup      | Bluegill Sunfish              | LC <sub>50</sub> = 34 mg/L <sup>b</sup> , 96-hour<br>NOEC = 21 mg/L                | Death    | Giesy et al., 2000 |
| Acute Toxicity         | Roundup      | Channel catfish               | LC <sub>50</sub> = 39 mg/L, 96-hour<br>NOEC = 23 mg/L                              | Death    | Giesy et al., 2000 |
| Acute Toxicity         | Roundup      | Channel catfish, adult        | LC <sub>50</sub> = 42.0 mg/L <sup>b</sup> , 96-hour                                | Death    | Giesy et al., 2000 |
| Acute Toxicity         | Roundup      | Coho Salmon, fry              | LC <sub>50</sub> = 42 mg/L, 96-hour                                                | Death    | Giesy et al., 2000 |
| Acute Toxicity, Static | Honcho® Plus | Rainbow Trout                 | LC <sub>50</sub> = 42 mg/L, 96-hour                                                | Death    | Monsanto, 2007d    |
| Acute Toxicity         | Roundup      | Rainbow Trout, Natural Waters | LC <sub>50</sub> = 52 mg/L, 96-hour                                                | Death    | Giesy et al., 2000 |

<sup>a</sup> Values are derived from a similar formulation

<sup>b</sup> Value from data sources corrected to mg roundup/L

<sup>c</sup> Values for soft (creek) and hard (lake) water, respectively

<sup>d</sup> Derived from an acute LC<sub>50</sub>/acute NOEC ratio of 5

#### 4.8.3 Acute Fish Toxicity to AMPA

The acute fish toxicity of AMPA is summarized in table N-34 below. The 4-day LC<sub>50</sub> value was established to be 520 mg AMPA/L while the NOEC was 33 mg AMPA/L.

**Table N-34. Acute Fish Toxicity to AMPA**

| Study Type<br>(% a.i. if provided) | Species       | Result                                              | Endpoint     | Reference          |
|------------------------------------|---------------|-----------------------------------------------------|--------------|--------------------|
| 4-day                              | Rainbow trout | NOEC = 33 mg AMPA/L;<br>LC <sub>50</sub> = 520 mg/L | Not reported | Giesy et al., 2000 |

#### 4.8.4 Chronic Fish Toxicity to Glyphosate

The chronic toxicity of glyphosate to fathead minnow and rainbow trout is summarized in table N-35. Chronic toxicity values for saltwater fish were not reported. The Maximum Allowable Toxicant Concentration (MATC) for fathead minnow was determined to be greater than 25.7 mg/L glyphosate (87.3% a.i.) (US EPA, 1993). This study was a full life-cycle toxicity study, and fish were able to reproduce normally at the identified MATC. A 21-day chronic study in rainbow trout identified a NOEC of 52 mg/L (Giesy, et al., 2000).

**Table N-35. Chronic Fish Toxicity to Glyphosate**

| Study Type<br>(% a.i. if provided) | Species        | Result                                           | Endpoint                                        | Reference          |
|------------------------------------|----------------|--------------------------------------------------|-------------------------------------------------|--------------------|
| Chronic (87.3%), life-cycle        | Fathead Minnow | MATC > 25.7 mg/L                                 | range and time frame exposure time not reported | US EPA, 1993       |
| <i>Tested as acid:</i>             |                |                                                  |                                                 |                    |
| Chronic                            | Fathead Minnow | NOEC = 26 mg a.e./L, 255-day, range not reported | Survival, growth, or reproduction               | Giesy et al., 2000 |
| Chronic, flow-through              | Rainbow trout  | NOEC = 52 mg a.e./L, 21-day, range not reported  | Not Reported                                    | Giesy et al., 2000 |

MATC= Maximum acceptable toxicant concentration

#### 4.8.5 Chronic Fish Toxicity to Glyphosate Herbicide Formulations

A single study is available assessing the toxicity of glyphosate formulations to freshwater fish. A 21-day chronic toxicity study with Roundup identified a NOEC of 2.4 mg/L for rainbow trout. Details of this study are presented in table N-36. Data addressing the toxicity of glyphosate formulations to saltwater fish was not reported.

**Table N-36. Chronic Fish Toxicity to Glyphosate Herbicide Formulation**

| Study Type | Formulation | Species       | Result                  | Reference          |
|------------|-------------|---------------|-------------------------|--------------------|
| Chronic    | Roundup     | Rainbow trout | NOEC = 2.4 mg/L, 21-day | Giesy et al., 2000 |

## 4.9 Saltwater and Marine Species Toxicity

Several acute toxicity tests were conducted on saltwater and marine organisms for exposure to glyphosate and its formulations. Per the US EPA's 1993 RED for Glyphosate, "since there is such an extensive data set for this chemical, the Agency can determine that glyphosate demonstrates low toxicity to fish and oyster species, and therefore is waiving the marine fish and oyster acute toxicity studies on the formulated product". The toxicity study results are discussed in sections 4.9.1.1 through 4.9.3.1.

### 4.9.1 Acute Saltwater and Marine Species Toxicity to Glyphosate

The acute toxicity of glyphosate to marine and estuarine organisms is summarized in table N-37. The most sensitive marine species to glyphosate was *Acartia tonsa* with a 48-hour LC<sub>50</sub> of 35.3 mg/L (tested as acid) (Tsui and Chu, 2003). The grass shrimp was reported to have a 96-hour LC<sub>50</sub> of 281 ppm (US EPA, 1993). The 48-hour TL<sub>50</sub> for Atlantic Oyster was determined to be > 10 mg/L (US EPA, 1993). The 48-hour TL<sub>50</sub> for Fiddler crab was determined to be 935 ppm (US EPA, 1993).

**Table N-37. Acute Saltwater and Marine Species Toxicity to Glyphosate**

| Study Type<br>(% a.i. if<br>provided) | Species                            | Result                                                                                  | Endpoint     | Reference                       |
|---------------------------------------|------------------------------------|-----------------------------------------------------------------------------------------|--------------|---------------------------------|
| Acute (96.7%)                         | Atlantic oyster                    | TL <sub>50</sub> = > 10 mg/L, 48-hour, range not reported                               | Death        | US EPA, 1993 <sup>a</sup>       |
| Acute (96.7%)                         | Grass shrimp                       | LC <sub>50</sub> = 281 ppm (207-381), 96-hour                                           | Death        | US EPA, 1993 <sup>b</sup>       |
| Acute (96.7%)                         | Fiddler crab                       | LC <sub>50</sub> = 934 ppm (555-1570), 96-hour                                          | Death        | US EPA, 1993 <sup>b</sup>       |
| <i>Tested as acid:</i>                |                                    |                                                                                         |              |                                 |
| Acute                                 | <i>Acartia tonsa</i>               | LC <sub>50</sub> (95% CI) = 35.3 mg/L (30.9-40.3); 48-hour                              | Death        | Tsui and Chu, 2003              |
| Acute                                 | <i>Cassostrea virginica</i> , eggs | Toxicity Value <sup>c</sup> = >10 mg/L, 48-hour, range not reported<br>NOEC = 10 mg/L   | Not Reported | Giesy et al., 2000 <sup>a</sup> |
| Acute                                 | <i>Mysidopsis bahia</i>            | Toxicity Value <sup>c</sup> = >1000 mg/L, 4 day, range not reported                     | Not Reported | Giesy et al., 2000              |
| Acute                                 | <i>Palaemonetes vulgaris</i>       | Toxicity Value <sup>c</sup> = 281 mg/L, 4 day, range not reported<br>NOEC = 210 mg/L    | Not Reported | Giesy et al., 2000 <sup>b</sup> |

<sup>a</sup> Bentley, R. (1973b) as cited in US EPA, 1993 and Bionomics (1973a) as cited in Giesy et al., 2000 are believed to reference identical studies, but this can not be confirmed with available data. Therefore, both studies are listed.

<sup>b</sup> Bentley, R. (1973a) as cited in US EPA, 1993 and Bionomics (1973b) as cited in Giesy et al., 2000 are believed to reference identical studies, but this can not be confirmed with available data. Therefore, both studies are listed.

<sup>c</sup> Values were not specified as EC<sub>50</sub> or LC<sub>50</sub>.

#### 4.9.2 Acute Saltwater and Marine Species Toxicity to Glyphosate Herbicide Toxicity

One study is available addressing the toxicity of Roundup to *Acartia tonsa*. A 48-hour LC<sub>50</sub> of 1.77 mg/L was determined for *Acartia tonsa* treated with Roundup. This study is summarized in table N-38.

**Table N-38. Acute Saltwater and Marine Species Toxicity to Glyphosate Herbicide Formulation**

| Study Type | Species              | Result                                                     | Endpoint | Reference          |
|------------|----------------------|------------------------------------------------------------|----------|--------------------|
| Acute      | <i>Acartia tonsa</i> | LC <sub>50</sub> (95% CI) = 1.77 mg/L (1.33-2.34); 48-hour | Death    | Tsui and Chu, 2003 |

#### 4.9.3 Chronic Saltwater and Marine Species Toxicity to Glyphosate and Glyphosate Herbicide Toxicity

No studies were identified that investigated chronic toxicity in saltwater or marine species.

### 4.10 Risk Assessment and Characterization

Risk characterization integrates the results of the exposure and ecotoxicity data to evaluate the likelihood of adverse ecological effects. The means of this integration is called the quotient method. Risk quotients (RQs) are calculated by dividing exposure estimates by acute and chronic ecotoxicity values ( $RQ = \text{Exposure}/\text{Toxicity}$ ).

RQs are then compared to the US EPA's levels of concern (LOCs) presented in table N-39 below. These LOCs are used by US EPA's Office of Pesticide Programs to analyze potential risk to nontarget organisms and the need to consider regulatory action. The criteria indicate that a pesticide used as directed has the potential to cause adverse effects on nontarget organisms. LOCs currently address the following risk presumption categories: (1) **acute** – potential for acute risk to non-target organisms which may warrant regulatory action in addition to restricted use classification, (2) **acute restricted use** – the potential for acute risk to non-target organisms, but may be mitigated through restricted use classification, (3) **acute endangered species** – endangered species may be adversely affected by use, (4) **chronic risk** – the potential for chronic risk may warrant regulatory action, endangered species may potentially be affected through chronic exposure, (5) **non-endangered plant risk** – potential for effects in non-target plants, and (6) **endangered plant risk** – potential for effects in endangered plants. Currently, US EPA does not perform assessments for chronic risk to plants, acute or chronic risks to nontarget insects, or chronic risk from granular/bait formulations to birds or mammals.

The ecotoxicity test values (measurement endpoints) used in the acute and chronic risk quotients are derived from required studies. Examples of ecotoxicity values derived from short-term laboratory studies that assess acute effects are: (1) LC<sub>50</sub> (fish and birds), (2) LD<sub>50</sub> (birds and mammals), (3) concentration that causes an effect in 50 percent of the test animals (EC<sub>50</sub>) (aquatic plants and aquatic invertebrates), and (4) concentration that causes an effect in 25 percent of the test animals concentration (EC<sub>25</sub>) (terrestrial plants). Examples of toxicity test effect levels derived from the results of long-term laboratory studies that assess chronic effects

are: (1) lowest observed adverse effect concentration (LOAEC) (birds, fish, and aquatic invertebrates) and (2) no observed adverse effect concentration (NOAEC) (birds, fish and aquatic invertebrates). For birds and mammals, the NOAEC generally is used as the ecotoxicity test value in assessing chronic effects, although other values may be used when justified. However, the NOAEC is used if the measurement endpoint is production of offspring or survival.

**Table N-39. Risk Presumption Categories**

| <b>Risk Presumption for Terrestrial Animals</b>                                                                                         | <b>LOC</b> |
|-----------------------------------------------------------------------------------------------------------------------------------------|------------|
| Acute: Potential for acute risk for all non-target organisms                                                                            | >0.5       |
| Acute Restricted Use: Potential for acute risk for all non-target organisms, but may be mitigated through restricted use classification | >0.2       |
| Acute Endangered Species: Endangered species may be adversely affected by use                                                           | >0.1       |
| Chronic Risk: Potential for chronic risk may warrant regulatory action                                                                  | >1         |
| <b>Risk Presumption for Aquatic Organisms</b>                                                                                           | <b>LOC</b> |
| Acute: Potential for acute risk for all non-target organisms                                                                            | >0.5       |
| Acute Restricted Use: Potential for acute risk for all non-target organisms, but may be mitigated through restricted use classification | >0.1       |
| Acute Endangered Species: Endangered species may be adversely affected by use                                                           | >0.05      |
| Chronic Risk: Potential for chronic risk may warrant regulatory action                                                                  | >1         |
| <b>Risk Presumption for Terrestrial and Aquatic Plants</b>                                                                              | <b>LOC</b> |
| Potential for risk for all non-endangered and endangered plants                                                                         | >1         |

#### *4.10.1 Exposure and Risk to Nontarget Terrestrial Animals*

Exposure to nontarget terrestrial organisms was estimated using the Tier 1 T-REX (Terrestrial Residue EXposure) simulation model (version 1.2.3) based on the maximum proposed application rate, re-application interval, and the default foliar dissipation half-life of 35 days at a rate of 1.99 lb ai/acre, applied four times at 30 day intervals. Residues on various terrestrial food items ranged from 60.53 to 968.42 mg/kg diet (US EPA, 2005).

##### **4.10.1.1 Terrestrial Exposure Modeling and Risk Characterization**

This spreadsheet-based model calculates the residues on avian and mammalian food items along with the dissipation rate of a chemical applied to foliar surfaces (for single or multiple applications) in order to estimate acute and reproductive risk quotients(US EPA, 2005). The methods used by T-REX to estimate risk from consumption of selected contaminated food items is described below. For this analysis, T-REX calculates estimated environmental concentrations (EECs) and risk quotients based on both the upper bound and mean residue concentrations as presented by Hoerger and Kenaga (1972) and modified by Fletcher et al. (1994). Based on the estimated dietary residue concentrations from the upper bound and mean Kenaga values, T-REX calculates the associated doses for various size classes of birds and mammals. Both the dietary

concentration (mg/kg-dietary item) and the resulting estimated doses (mg/kg-bw) may be used for risk estimation. The EECs for terrestrial exposure were derived from the Kenaga nomograph based on a large set of field residue data. The EECs presented in table N-40 were calculated by the TREX Version 1.2.3 model and the corresponding avian acute and chronic RQs presented in tables N-40 and N-42 are based on the most sensitive subacute dietary LC<sub>50</sub>, single oral dose LD<sub>50</sub>, and NOAEC for birds.

**Table N-40. Dietary-based EECs Upper Bound Kenaga Values from TREX model**

| Food source                     | Estimate concentration glyphosate (ppm) |
|---------------------------------|-----------------------------------------|
| Short Grass                     | 968.42                                  |
| Tall Grass                      | 443.86                                  |
| Broadleaf plants/Small Insects  | 544.74                                  |
| Fruits/pods/seeds/Large insects | 60.53                                   |

Acute avian risk is assessed both by comparing the dietary LC<sub>50</sub> with residues on avian food items and by comparing the acute oral LD<sub>50</sub> with estimated daily doses calculated from residues on avian food items. Calculations for oral dose risk quotients are based on a Northern bobwhite quail oral acute LD<sub>50</sub> of >2000 mg glyphosate/kg body weight. Calculations for acute dietary-based risk quotients are based on a bobwhite quail subacute dietary LC<sub>50</sub> of 4640 mg/kg diet. There were no statistically significant results in the bobwhite quail reproductive toxicity and resulted in a chronic NOAEC of > 1000 mg/kg diet. These endpoints are not adjusted for body weight.

**Table N-41. Avian Dose-based RQs from TREX model**

| Dose-based RQs<br>(Dose-based EEC/adjusted LD <sub>50</sub> ) | Avian Acute RQs |       |        |
|---------------------------------------------------------------|-----------------|-------|--------|
|                                                               | 20 g            | 100 g | 1000 g |
| Short Grass                                                   | 0.77            | 0.34  | 0.11   |
| Tall Grass                                                    | 0.35            | 0.16  | 0.05   |
| Broadleaf plants/sm insects                                   | 0.43            | 0.19  | 0.06   |
| Fruits/pods/seeds/lg insects                                  | 0.05            | 0.02  | 0.01   |

RQs were calculated, and where the resulting quotient is lower than the LOCs, thus the acute risk is minimal for those scenarios, routes of exposure and food items. In cases where the RQs exceed an LOC, they are not presented because there is no definitive lethal dose. In those cases, the estimated oral dose is compared with the dose level at which no mortality occurred. If the estimated field oral dose does not exceed the laboratory derived dose of no mortality effect, it is concluded that potential for acute risk is minimal. If the estimated field dose exceeds the laboratory dose of no mortality effect, the conclusion is left as uncertain because acute risk cannot be ruled out, nor can it be concluded as likely. Oral dose-based scenarios are calculated by dividing the consumption-weighted equivalent dose by the body weight-adjusted LD<sub>50</sub>. The acute RQs for birds based on single-oral dose oral studies are summarized in table N-41.

**Table N-42. Avian Dietary-based RQs from TREX model**

| Dietary-based RQs<br>(Dietary-based EEC/LC50 or NOAEC) | RQs   |         |
|--------------------------------------------------------|-------|---------|
|                                                        | Acute | Chronic |
| Short Grass                                            | 0.21  | 0.97    |
| Tall Grass                                             | 0.10  | 0.44    |
| Broadleaf plants/Small Insects                         | 0.12  | 0.54    |
| Fruits/pods/seeds/Large insects                        | 0.01  | 0.06    |

These peak EECs resulted in no LOC exceedences, except for the birds whose diet consists of broad leaf plants and small insects; however this exceedence is minor with a RQ of 0.12, which is slightly greater than the LOC (>0.1) for Acute Endangered Species: Endangered species may be adversely affected by use. The EEC is based on worst case scenario and very minor; therefore, it is not considered a risk. Consumption-weighted doses for mammals based on weight class at four applications of 1.99 lb ai/acre with 35 day foliar half-life resulted in the risk quotients presented in tables N-43 and N-44.

**Table N-43. Mammalian Dose-Based Risk Quotients (RQ) from TREX model**

| Dose-based RQs<br>(Dose-based EEC/LD50 or NOAEL) | 15 g mammal |         | 35 g mammal |         | 1000 g mammal |         |
|--------------------------------------------------|-------------|---------|-------------|---------|---------------|---------|
|                                                  | Acute       | Chronic | Acute       | Chronic | Acute         | Chronic |
| Short Grass                                      | 0.10        | 2.40    | 0.08        | 2.05    | 0.04          | 1.10    |
| Tall Grass                                       | 0.04        | 1.10    | 0.04        | 0.94    | 0.02          | 0.50    |
| Broadleaf plants/small insects                   | 0.05        | 1.35    | 0.05        | 1.15    | 0.03          | 0.62    |
| Fruits/pods/large insects                        | 0.01        | 0.15    | 0.01        | 0.13    | 0.00          | 0.07    |
| Seeds (granivore)                                | 0.00        | 0.03    | 0.00        | 0.03    | 0.00          | 0.02    |

Calculations for both oral dose-based and dietary-based risk quotients were based on an acute laboratory rat LD<sub>50</sub> value of >4320 mg/kg bw and a 2-generation chronic reproductive effect NOAEC of 175 mg/kg bw. For chronic oral dose-based RQ calculations, the NOAEC (3500 mg/kg diet) was converted to a NOAEL (175 mg/kg body weight) based on a standard FDA lab rat conversion (US EPA, 2006a).

**Table N-44. Mammalian Dietary-Based Risk Quotients (RQ) from TREX model**

| Dietary-based RQs<br>(Dietary-based EEC/LC50 or NOAEC) | Mammal RQs |         |
|--------------------------------------------------------|------------|---------|
|                                                        | Acute      | Chronic |
| Short Grass                                            | <0.1       | 0.28    |
| Tall Grass                                             | <0.1       | 0.13    |
| Broadleaf plants/small insects                         | <0.1       | 0.16    |
| Fruits/pods/seeds/large insects                        | <0.1       | 0.02    |

Risk to non-target insects is expected to be low; the honey bee LD<sub>50</sub> is very high >100 µg/honeybee; therefore, glyphosate is not considered a risk to honeybee and other non-target arthropods.

#### 4.10.2 Exposure and Risk to Aquatic Organisms

Exposure to aquatic species was estimated using GENEEC (GENeric Estimated Exposure Concentration) Version 2.0 (US EPA, 2001b) as the Tier I simulation model. GENEEC is a Tier 1 simulation model that estimates the peak value which occurs on the day of a single large rainstorm event as well as multiple day averages over periods of 4, 21, 60 and 90 days. The magnitude of the peak concentration is the result of how fast the chemical dissipates (degradation; partitioning) in the field. The multiple day average over periods of four to 90 days reflect the dissipation (such as degradation and partitioning) of the chemical that takes place in the water body. These peak and average concentrations are then compared with the appropriate toxicity tests for aquatic plants and animals.

The peak concentration of glyphosate in a pond receiving runoff from a drainage basin treated 100 percent with glyphosate would be 15.66 µg/L (ppb) for Honcho® at the highest application rate. This does not exceed any LOCs, and longer term exposures would be lower; therefore risk is presumed to be below thresholds of concern. The input parameters for and the results of this model are presented in the following section.

##### 4.10.2.1 Aquatic Exposure Modeling

GENEEC Version 2.0 (US EPA, 2001b) was used to estimate the EECs in surface water in order to assess exposure in aquatic ecosystems.

These estimated environmental concentrations were based on the application rates proposed in the labels for uses on tolerant, gene modified alfalfa. It was assumed that glyphosate was applied in four sequential applications; at least 7 days apart to an annual total maximum of 7.98 lbs glyphosate equivalent per acre and that each single application is assumed to be 1.99 lbs glyphosate equivalents per acre.

Environmental fate input parameters were selected in accordance with EFED's "Guidance for Selecting Input Parameters in Modeling the Environmental Fate and Transport of Pesticides, Version II" (February 28, 2002; [http://www.epa.gov/oppefed1/models/water/input\\_guidance2\\_28\\_02.htm](http://www.epa.gov/oppefed1/models/water/input_guidance2_28_02.htm)) and are presented below.

Environmental Fate Input Parameters:

- Solubility in water (mg/L): 12,000
- Soil Organic Carbon Partition Coefficient ( $K_d$ ): 62<sup>48</sup>
- Aerobic soil metabolism half-life (days): 2<sup>49</sup>
- Non wetted ground high boom fine spray application with 0 ft no spray zone, and 0 in depth incorporation
- Aerobic aquatic metabolism half-life (days): 7<sup>50</sup>
- Photolytic half-life (days): 0

<sup>48</sup> The values for  $K_d$  were the lowest values determined from a non-sandy soil, for Drummer silty clay loam (US EPA, 1993)

<sup>49</sup> The value of aerobic soil metabolism half-life for glyphosate equivalents is based on data from US EPA, 1993.

<sup>50</sup> The value of aerobic aquatic metabolism half-life for glyphosate equivalents is based on data from US EPA, 1993.

- Hydrolytic half-life (days): 0

#### Aquatic Risk Characterization

Risk presumptions and the corresponding acute and chronic RQs and LOCs are tabulated in tables N-45 and N-46. The values in these tables are based on results of submitted studies and data from peer-reviewed literature, as indicated by the notes following each table. None of the acute or chronic RQs for glyphosate exceeded LOCs for any of the most sensitive aquatic species tested.

**Table N-45. Acute Risk Quotients for Glyphosate and Most Sensitive Species**

| Species                               | EEC<br>(µg/L) <sup>a</sup> | Toxicity<br>(µg/L)  | Acute RQ | Acute LOCs<br>Exceeded |
|---------------------------------------|----------------------------|---------------------|----------|------------------------|
| <b>Amphibians</b>                     |                            |                     |          |                        |

<sup>e</sup> Tsui and Chu, 2003

#### 4.11 Summary of Findings

In general, glyphosate has a low toxicity to animals; however, the end use herbicide formulations, in some cases, are more toxic. The data suggest certain surfactants in glyphosate formulations result in a higher toxicity to amphibians, aquatic invertebrates, and fish. The dose-response assessment for fish is substantially complicated by information indicating that some fish species such as salmonids are more sensitive to glyphosate than other species. Glyphosate appears to be about equally toxic to both algae and aquatic macrophytes.

For GT alfalfa use, exposure does not result in risk exceeding LOCs; however, the end use herbicide concentration could not be determined and without an estimate of environmental concentrations, quantitative risk values cannot be calculated. The 2008 risk assessment published by the EPA for the effects of glyphosate, its salts, and glyphosate herbicide formulations found indirect effects on the CRLF at application rates more than twice the application rate of glyphosate on GT alfalfa.

## 5.0 Alfalfa Other Pesticide Ecotoxicity data

### 5.1 Alfalfa Pesticide Comparative Ecotoxicity

## 5.2 Comparative Environmental Impact of Glyphosate and Other Herbicides Used on Alfalfa

Glyphosate is considered to be more environmentally and toxicologically benign than many of the herbicides that it replaces in GT crops (Brookes and Barfoot, 2006). Peterson and Hulting (2004) examined the ecological risks of glyphosate and 15 other herbicides used on spring wheat populations in the northern U.S. Great Plains (MN, ND, SD, WY, and MT). Glyphosate is used in GT wheat systems, while the 15 other herbicides are widely used on spring wheat. The herbicides were as follows: 2,4-D, bromoxynil, clodinafop, clopyralid, dicamba, fenoxaprop, flucarbazone, MCPA, metasulfuron, thifensulfuron, tralkoxydim, triallate, triasulfuron, tribenuron, and trifluralin. A Tier 1 quantitative risk assessment method was used to evaluate the acute dietary risk to birds and wild mammals, the acute risk to aquatic vertebrates, aquatic invertebrates, and aquatic plants, and the effects on seedling emergence and vegetative vigor to non-target terrestrial plants. Estimated groundwater exposures to the 16 herbicides (including glyphosate) were assessed. The assessment did not include chronic risks, risks to estuarine or marine animals, or risks to nontarget insect pollinators (Peterson and Hulting, 2004). The ecological risks for the 15 herbicides relative to glyphosate were highly variable, with glyphosate having less relative risk to non-target terrestrial and aquatic plant life and groundwater than most other active ingredients. The study predicted that glyphosate use in GT crops will be less toxic to terrestrial and aquatic wildlife than several of the herbicides which it replaces (Peterson and Hulting, 2004).

The environmental impact of other herbicides used on alfalfa in comparison to glyphosate includes an assessment of pesticide active ingredient use, as well as the assessment of the specific pesticides used via an indicator known as the Environmental Impact Quotient (EIQ). This universal indicator, developed by Kovach et al (1992 & updated annually), effectively integrates the various environmental impacts of individual pesticides into a single indicator value of impact; however, it does not take into account all environmental issues/impacts. This provides a balanced assessment of the impact of herbicides on the environment as it draws on key toxicity and environmental exposure data related to individual products (as applicable to impacts on farm workers, consumers and ecology), thus, providing a consistent but a fairly comprehensive measure of environmental impact as applied by Brookes and Barfoot in 2006 for genetically modified crop impact assessments.

The sixteen following herbicides are used in conventional alfalfa: 2,4-DB, benefin, bromoxynil, clethodim, diuron, EPTC, hexazinone, imazamox, imazethapyr, metribuzin, norfluzon, paraquat, pronamide, sethoxydim, terbacil, and trifluralin. The following four herbicides are suggested to remove a stand of GT alfalfa 2,4-D, dicamba, clopyralid, and picloram. These herbicides are evaluated for their environmental impact via a method developed by New York State Integrated Pest Management Program, where the EIQ is formulated based on toxicity and environmental fate data for several herbicides and insecticides used on agricultural practices (Kovach et al., 1992 & updated annually). The EIQ has been used to organize the extensive toxicological data available on pesticides and compare these pesticides even though these pesticides have several modes of actions. The formula for determining the EIQ value of individual pesticides is listed below and is the average of the farm worker, consumer, and

ecological components (Kovach et al., 1992 & updated annually). Further discussion on the development and methods can be found at <http://nysipm.cornell.edu/publications/eiq/default.asp>

$$EIQ = \{C[(DT*5)+(DT*P)] + [(C*((S+P)/2)*SY)+(L)] + [(F*R)+(D*((S+P)/2)*3)+(Z*P*3)+(B*P*5)]\} / 3$$

DT = dermal toxicity,

C = chronic toxicity,

SY = systemicity,

F = fish toxicity,

L = leaching potential,

R = surface loss potential,

D = bird toxicity,

S = soil half-life,

Z = bee toxicity,

B = beneficial arthropod toxicity,

P = plant surface half-life.

The lower the EIQ values the less environmental impact the herbicide exerts on the environment, as table N-50 illustrates besides EPTC glyphosate is the most environmentally benign. Data on the herbicide 2,4-DB is not in the EIQ calculations. 2,4-DB is a selective systemic herbicide in the chlorophenoxy family, in plants it is converted to 2,4-D; however, relatively little data is available on 2,4-DB and is absent in the EIQ calculations. Ecotoxicologically, 2,4-DB was considered a risk to terrestrial plants (from spray drift and run off after aerial and ground applications), freshwater fish (threatened and endangered species), and small and medium mammals (threatened and endangered species) by EPA as reported in the Reregistration Eligibility Report (2005a) when using the maximum application rate on alfalfa. The environmental fate properties of the 20 pesticides are discussed in section 3.2 and the ecotoxicology in section 5.1 above.

As is evident from table N-50 all but EPTC have higher EIQ values and therefore pose a higher risk to the environment.

**Table N-50. Environmental Impact Quotient Comparison of Alfalfa Herbicides (Kovach et al., 1992 & updated annually)**

| Herbicide         | EQ Total Value | Farm worker EQ | Consumer EQ  | Ecology EQ   |
|-------------------|----------------|----------------|--------------|--------------|
| <i>Glyphosate</i> | 15.30          | 8.00           | 5.00         | 33.00        |

These calculations are defined by Kovach and colleagues as such:

Farm worker risk is defined as the sum of applicator exposure (DT\*5) plus picker exposure (DT\*P) times the long-term health effect or chronic toxicity (C). Chronic toxicity of a specific pesticide is calculated as the average of the ratings from various long-term laboratory tests conducted on small mammals. These tests are designed to determine potential reproductive effects (ability to produce offspring), teratogenic effects (deformities in unborn offspring), mutagenic effects (permanent changes in hereditary material such as genes and chromosomes), and oncogenic effects (tumor growth). Within the farm worker component, applicator exposure is determined by multiplying the dermal toxicity (DT) rating to small laboratory mammals (rabbits or rats) times a coefficient of five to account for the increased risk associated with handling concentrated pesticides. Picker exposure is equal to dermal toxicity (DT) times the rating for plant surface residue half-life potential (the time required for one-half of the chemical to break down). This residue factor takes into account the weathering of pesticides that occurs in agricultural systems and the days to harvest restrictions that may be placed on certain pesticides.

The consumer component is the sum of consumer exposure potential ( $C*((S+P)/2)*SY$ ) plus the potential groundwater effects (L). Groundwater effects are placed in the consumer component because they are more of a human health issue (drinking well contamination) than a wildlife issue. Consumer exposure is calculated as chronic toxicity (C) times the average for residue potential in soil and plant surfaces (because roots and other plant parts are eaten) times the systemic potential rating of the pesticide (the pesticide's ability to be absorbed by plants).

The ecological component of the model is composed of aquatic and terrestrial effects and is the sum of the effects of the chemicals on fish ( $F \cdot R$ ), birds ( $D \cdot ((S+P)/2) \cdot 3$ ), bees ( $Z \cdot P \cdot 3$ ), and beneficial arthropods ( $B \cdot P \cdot 5$ ). The environmental impact of pesticides on aquatic systems is determined by multiplying the chemical toxicity to fish rating times the surface runoff potential of the specific pesticide (the runoff potential takes into account the half-life of the chemical in surface water).

The impact of pesticides on terrestrial systems is determined by summing the toxicities of the chemicals to birds, bees, and beneficial arthropods. Because terrestrial organisms are more likely to occur in commercial agricultural settings than fish, more weight is given to the pesticidal effects on these terrestrial organisms. Impact on birds is measured by multiplying the rating of toxicity to birds by the average half-life on plant and soil surfaces times three. Impact on bees is measured by taking the pesticide toxicity ratings to bees times the half-life on plant surfaces times three. The effect on beneficial arthropods is determined by taking the pesticide toxicity rating to beneficial natural enemies times the half-life on plant surfaces times five. Because arthropod natural enemies spend almost all of their life in agroecosystem communities (while birds and bees are somewhat transient), their exposure to the pesticides, in theory, is greater. To adjust for this increased exposure, the pesticide impact on beneficial arthropods is multiplied by five. Mammalian wildlife toxicity is not included in the terrestrial component of the equation because mammalian exposure (farm worker and consumer) is already included in the equation, and these health effects are the results of tests conducted on small mammals such as rats, mice, rabbits, and dogs.

After the data on individual factors were collected, pesticides were grouped by classes (fungicides, insecticides/miticides, and herbicides), and calculations were conducted for each pesticide. When toxicological data were missing, the average for each environmental factor within a class was determined, and this average value was substituted for the missing values. Thus, missing data did not affect the relative ranking of a pesticide within a class.

Researchers at Ghent University developed the pesticide occupational and environmental risk (POCER) indicator (Devos et al., 2008). POCER is a similar concept as EIQ and includes ten modules; (1) risk to pesticide operator; (2) risk to worker; (3) risk to bystander; (4) persistence in the soil; (5) risk of ground water contamination; (6) acute risk to aquatic organisms; (7) acute risk to birds; (8) acute risk to bees; (9) acute risk to earthworms; and (10) risk to beneficial arthropods. The toxicological reference values used in the effect assessment are certified endpoints defined in Annex VI of Directive 91/414/EEC. Using GT corn and non-GT corn as an example, the POCER values for glyphosate or glufosinate used alone were about one sixth less than other herbicide regimes (31 regimes were evaluated). This environmental benefit of glyphosate over other herbicides was attributed to lower potential for leaching and lower toxicity to aquatic organisms (Devos et al., 2008).

Using the above standardized methods for ranking environmental impact, researchers have concluded that glyphosate is less harmful to the environment than many other herbicides and that the shift of herbicide use has resulted in a net lower environmental impact from herbicides.

### 5.3 Summary of Findings

The increase in glyphosate due to adoption of GT crops in 1996 has caused concern. Ecological effects, exposures, and risks from direct exposure to the 20 alfalfa herbicides were evaluated in this section, section 3.4 evaluated the chemical fate. For all ecological receptors, the most sensitive toxicity endpoints that were publicly available were used for the EIQ assessment. Data sources for toxicity for each ecological receptor are referenced in each table. As table N-50 illustrates all of the common alfalfa herbicides pose a higher risk to the environment than glyphosate, excluding EPTC. Thus with the possible replacement or decreased reliance on these pesticides with glyphosate on GT alfalfa the environmental risk is decreased. Risk analysis incorporates toxicity and exposure data and without integrating these factors the assessment is limited. However, performing comparative Tier 1 risk assessments of all 20 herbicides to glyphosate will only assess the worst case scenario making these assessments, general and not conclusive. Actual herbicide use rates vary with the season, geography, biology of the weeds in the area, and cultivator. It is clear glyphosate usage trends are increasing and that glyphosate is more toxicologically and environmentally benign than the pesticides glyphosate may be replacing.

## **Appendix N-2.**

## **Literature Search**

### **1.0 Literature Search Strategy**

Develop a risk assessment for increased glyphosate and other chemical usage on wildlife, amphibians, plants and ecosystems

#### **1.1 Purpose**

The purpose of this literature search is to locate references about the potential impacts to wildlife, amphibians, plants, and ecosystems from increased glyphosate and other chemical usage.

We propose that the following DIALOG databases be included in the search:

|                                    |                                                 |
|------------------------------------|-------------------------------------------------|
| File 5: BIOSIS                     | File 117: Water Resources                       |
| File 6: NTIS                       | Abstracts                                       |
| File 10: AGRICOLA                  | File 144: PASCAL                                |
| File 34: SciSearch                 | File 154: MEDLINE                               |
| File 41: Pollution Abstracts       | File 156:ToxFile                                |
| File 40: Enviroline                | File 245: WATERNET™                             |
| File 72: EMBASE                    | File 250: CAB Abstracts                         |
| File 76: Environmental Sciences    | File 266: Federal Research In Progress (FEDRIP) |
| File 79: Aqualine                  | File 399: CA SEARCH®: Chemical Abstracts®       |
| File 98: General Science Abstracts |                                                 |

Descriptions of these files are available at <http://library.dialog.com/bluesheets/>.

#### **1.2 Scope of Search**

The search will focus any published references after 1999. A reference list with abstracts will be screened for relevance to the ecotoxicity of glyphosate. English language only publications will be retrieved.

The following list will be retrieved and expanded upon.

#### **1.3 Strategy Overview**

A list of search parameters is listed below.

#### **1.4 Synonyms**

Glyphosate  
Glyphosate, isopropylamine salt

Glyphosate, sodium salt  
Glyphosate, potassium  
Glyphosate, ammonium  
Glyphosate, sulfosate  
*N*-(phosphonomethyl) glycine  
Roundup®  
Roundup Ultra®  
Roundup WeatherMAX  
Honcho®

## 1.5 Keywords

|                         |                      |
|-------------------------|----------------------|

## 1.7 Submission of Citations for Approval

Using reference management software, pooled information obtained from the various bibliographic databases will be screened to remove duplicates. Additionally, ICF will review the list prior to submission and eliminate any irrelevant citations. Information provided to US EPA will include the following (when available):

Author(s). Publication Year. Title. Source Document Name, Volume, Page Numbers.

Abstract

Descriptors/Identifiers (*i.e.*, keywords and subject headings)

## **Appendix O. Colony Collapse Disorder and Glyphosate-Tolerant Alfalfa**

# Colony Collapse Disorder and Glyphosate-Tolerant Alfalfa

## 1.0 Introduction

### 1.1 Overview of the Biology and Culture of Alfalfa

The biological and cultural characteristics of alfalfa are summarized by a Council for Agricultural Science and Technology Task Force Special Publication (CAST, 2008). Briefly, alfalfa (*Medicago sativa* L.) is an herbaceous short-lived perennial forage legume (CFIA, 2005; Lesins and Lesins, 1979). Introduced to the Americas it is the most important forage crop species in Canada and the U.S. and is widely adapted and grown in all 50 U.S. states. The three states with the largest amount of alfalfa hay acreage are South Dakota, Montana, and Wisconsin, according to the 2007 Census of Agriculture. Hybridization is restricted to certain species in the Genus *Medicago* and the crop relies on a variety of bee species for pollination (CAST, 2008). Alfalfa is self-incompatible and predominately outcrossing and is not capable of natural hybridization with any other species found in North America (CFIA 2005). Alfalfa grows optimally in fertile, well-drained soils but it can also survive as feral plants growing outside of cultivation (Kendrick et al., 2005). In the U.S., the vast majority of alfalfa is harvested as forage for use as animal feed. Forage is harvested as dry hay, haylage, and greenchop and grazed in pastures, which will be collectively referred to herein as “hay” or “forage”. In 2007, approximately 23.5 million acres of alfalfa were grown in the U.S. (USDA-NASS, 2007). Only about 122,000 acres (0.5%) of the total U.S. alfalfa production acreage is harvested for seed production (USDA-NASS, 2007). Approximately 70% of all alfalfa seed grown in the U.S. is used for the establishment of domestic hay fields, with the balance sold in export markets (CAST, 2008; Putnam, 2006). Because weeds and pests consistently reduce the yield of pure alfalfa and negatively affect forage nutritional quality, virtually all alfalfa planting seed produced in the U.S. is grown using insecticides and or herbicides (Peters and Linscott, 1988) which precludes its use for organic or sprouting (i.e., food) purposes.

### 1.2 Alfalfa Forage Production

In North America, alfalfa can be sown when there is available moisture and a sufficient frost-free growth period. Most alfalfa is predominately sown in the spring, except in the western and southern U.S. where fall planting is more common (Hower et al., 1999). Once alfalfa seedlings are established, the hay fields are harvested two to ten times per year depending upon location and seasonal climate. Following forage cutting, re-growth is from buds associated with the perennial root structure (the crown) or the lower stem nodes. Flower bud initiation requires long day length. Alfalfa forage production fields remain economically viable for approximately three to five years after initial planting.

Most alfalfa fields in the U.S. are harvested in the pre-flower (vegetative) or early bloom stages of maturity to optimize forage yield and feeding quality. Mature alfalfa stems with open flowers or seed result in poor feed quality and significantly reduced market value (Sheaffer et al., 1988). Accordingly, most alfalfa forage producers have a strong economic disincentive to allow extensive flowering or mature seed set in hay production. Since forage production practices periodically remove the entire plant canopy where flowers, pollen or seed might form, greater than 98% of alfalfa in the U.S. is without flowers (vegetative) or in an early stage of flower development (CAST, 2008; Sheaffer et al., 1988; Putnam, 2006; Putnam, 2007) at any given time. Alfalfa fields in flower are thus infrequent and sporadic. Exceptions are most notable in alfalfa seed production (seed increase) fields of the Western U.S. and in non-irrigated, low-input forage production fields in the Plains States wherein a combination of drought and the short growing season often limit forage yield and quality potential (McCaslin, 2007).

### 1.3 Alfalfa Seed Production -- The Role of Bees

Alfalfa seed production is a distinct commercial practice from forage production (Hanson et al., 1988). Alfalfa seed production requires a long growing season with very warm temperatures and very low humidity during seed ripening. Alfalfa seed yield is highly influenced by grower inputs, weeds, insect pests and seasonal weather fluctuations. Due to the limited number of skilled growers and suitable acres, U.S. alfalfa seed production occurs exclusively in niche areas of the western U.S. on approximately 100,000 to 120,000 acres that are of high value, intensively managed, and irrigated (USDA-NASS, 2007).

Alfalfa cultivars are developed by plant breeders using a combination of phenotypic and or genotypic recurrent selection to identify parent plants. Seeds of the cultivar (or variety) are produced commercially in spatial isolation from other cultivars (AOSCA, 2003). Cultivars are, with few exceptions, open-pollinated varieties. Alfalfa is not wind pollinated and it is very rarely self-pollinated (Teuber, 2007b; Viands et al., 1988). Cultivated (seed producing) alfalfa is exclusively bee cross-pollinated (CFIA, 2005; Olmstead and Wooten, 1987). Most professional seed producers use cultured bees and specialized equipment associated with bee culturing. The cost and availability of cultured pollinator bees is highly variable (many cultured bees are imported from western Canada). As seed is not desired on managed forage fields, pollination and bees are of no direct consequence or value to the hay crop, *per se*.

Alfalfa seed production fields are usually planted in the fall and mowed in late spring so that subsequent bloom within the field is uniform, synchronous and optimally timed for the warm dry season and optimal bee pollinator activity. Weed and in-crop volunteer plants are controlled using herbicides and cultivation prior to the start of pollination or after seed harvest. Insecticides, primarily for *Lygus spp.* control, and other pesticides are applied prior to bee release to avoid insecticide damage to bees (Hower et al., 1999). Flowering begins approximately in mid June. At approximately 50% flower (ca. early to mid July), cultured bees (discussed below) are gradually moved with their domicile or hive for local shelter into the seed field for pollination. The bees are allowed to pollinate the plants for approximately one month, the seeds are allowed to ripen for approximately four to six more weeks, and then, chemically desiccated or swathed several days prior to combining the seed. At the end of the pollination period and several weeks prior to field desiccation, the pollinating generation of bees is either at the end of

its lifecycle (leafcutter or alkali bees), or, in the case of honey bees, transported by the bee keeper to a different location to forage on fall-flowering plant species. Post-pollination, it takes approximately four to six weeks for the alfalfa seed to ripen and become physiologically mature under optimal seed production conditions (Bass et al., 1988). High winds and or drought stress may induce flowers to mechanically auto-pollinate; however, the resulting self-pollination (inbreeding) most commonly results in no seed or few seeds with inferior vigor (Viands et al., 1988). Seed is harvested in mid August to late September, depending on geography.

As mentioned earlier, alfalfa seed production is entirely dependent upon several different bee species to “trip” flowers (discussed in more detail below) and release pollen for ovule fertilization and seed production. Teuber et al. (2005) developed an extensive literature review on honey bee pollination in alfalfa. A general recent review of principles of bee pollination may be found in *Crop Pollination by Bees* (Delaplane and Mayer, 2000). A low frequency of feral solitary bee species may visit blooming alfalfa fields to collect pollen or nectar (Hammon et al. 2006); however in most alfalfa seed-growing areas, naturally occurring populations of alfalfa-pollinating bees are either nonexistent or at levels insufficient for adequate pollination (Arnett, 2002). Most professional seed producers use prudent, cultured bee management to control the bee species, bee hive field placement, bee stocking date(s) and bee stocking rate(s) and they are careful to apply bee compatible insecticides in their seed fields.

Honey bees (*Apis mellifera* L.) are used primarily in the irrigated valleys of the Desert Southwest (California, Arizona, etc.) and cultured alfalfa leafcutting bees, *Megachile rotundata* (F.), are used primarily in the cooler Pacific Northwest. In certain niche geographies where suitable climate and soil beds exist (e.g., southern Washington), permanent colonies of the ground-nesting alkali bee, *Nomia melanderi* Cockerell, contribute significantly to commercial alfalfa pollination, and are estimated to contribute 20% pollination for alfalfa seed fields proximal to an alkali bee bed. However, alkali bee pollination is often augmented by adding cultured leafcutter bees. Occasionally, some seed producers use a blend of two managed cultured bee species for pollination to increase the rate of seed set or shorten the pollination period. Feral honey bees and native bees including *Bombus* spp, *Osmia* spp, *Agapostomen* spp. and *Megachile* spp. can also be found visiting alfalfa flowers in varying numbers. These species may sometimes pollinate alfalfa flowers but their importance in alfalfa pollination is minor (Hammon et al., 2006; Arnett, 2002). Hammon et al. (2006) identified nine native bee species visiting alfalfa flowers in Colorado. In the northern, central and southern plains where a small portion of the U.S. alfalfa seed tonnage is produced, seed yield and grower inputs per acre are very low. In these marginal seed growing geographies, seed producers typically do not augment bee populations and typically rely on feral and native bee populations. Other non-bee insect pollinators are not effective pollinators of alfalfa; thus, some authors have estimated that about 60% of all pollinators in alfalfa hay and seed fields are honey bees (Morse and Calderone, 2000; Johnson, 2007).

Bee pollinator activity is required to simultaneously deposit non-self pollen onto the alfalfa flower’s stigma surface, rupture the protective stigmatic cuticle, and effect pollination (Teuber, 2007b; Viands et al., 1988). This process is called “tripping” and is triggered by bees visiting the flower to collect nectar or pollen. After it is tripped, the stigma of the flower becomes lodged into the groove of the standard petal of the flower. Because of the nonreversible tripping

mechanism within the alfalfa flower, each alfalfa flower may be pollinated only a single time by a single pollinating bee. Honey bees are hit in the head by this violent tripping process, which they learn to avoid by sipping nectar slantwise from the flower (Milius, 2007). Accordingly, honey bees demonstrate a strong behavioral aversion to foraging for nectar in flowering alfalfa (Arnett, 2002; Pitts-Singer, 2007; Teuber, et al., 2005). Because honey bees avoid the tripping mechanism they also are less efficient commercial alfalfa pollinators (Arnett, 2002; Cane, 2002). Indeed, Cane (2002) determined that honey bees only pollinate (“trip”) about 22 percent of the alfalfa flowers they visit. In non-seed production areas flowering weeds or other crop species are more important sources of nectar and pollen for honey bees (Arnett, 2002; Pitts-Singer, 2007; Teuber, et al., 2005). Researchers are working to improve honey bee pollination through selection of useful honey bee traits such as increased hive pollen storage, where in a typical honey bee hive only a small portion of the workers actually collect pollen instead of nectar (for honey). The hope is that bees selected for high pollen storage will also be good alfalfa pollen collectors, thus making them better pollinators (Mueller, 2008). Because of these shortcomings of the honey bee and competition from other crops for pollinating hives (e.g., almonds), alfalfa seed producers have increasingly used the alfalfa leafcutter bee for alfalfa pollination.

The leafcutter bee (*M. rotundata*) was accidentally introduced into North America from Eurasia in the 1930s and by the 1950s, entomologists recognized the bee as a superior pollinator of alfalfa (Greer, 1999; Bosch and Kemp, 2005). Currently, alfalfa leafcutting bees are the preferred bee pollinator for more than two-thirds of all alfalfa seed production acres in North America (Bosch and Kemp, 2005). In the 1970’s, leafcutter bee keepers started experiencing difficulty in maintaining leafcutter bee populations. Population losses (the difference between parental adults released and live progeny recovered) of 50% are now common in the Pacific Northwest. Leafcutter bees are increasingly being introduced from Canada to maintain adequate pollination for seed production. Chalkbrood, a disease caused by pathogenic fungus, *Ascosphaera* spp., is thought to be a major contributing factor negatively affecting leafcutter bee populations.

All bees have a limited range over which they will search to collect pollen. The maximum foraging radius for each of the three commercially available bee species *A. mellifera*, *M. rotundata*, and *N. melanderi* depends heavily on the abundance (or dearth) of nectar and pollen resources. Leafcutter bees have the shortest routine foraging radius (<1/4 mile), followed by the honey bee, and alkali bee (ca. 1 to 3 miles) (Arnett, 2003; Gathmann and Tschardt, 2002; Hammon et al., 2006; Teuber et al., 2005). Honey bees may infrequently transport alfalfa pollen and effect pollination up to 3 miles from the source (St. Amand et al., 2000; Teuber et al., 2004; Hammon et al. 2006). Accordingly, managed bee colonies are placed either in or in very close proximity to the crops they are intended to pollinate. Therefore, it is a common practice for certified and many non-certified seed producers to mitigate cross-pollination by unknown alfalfa pollen by using spatial field isolation and stocking their fields with recommended rates of cultured bees to synchronously and quickly pollinate the field and make it less attractive to feral bees. Likewise, conventional seed producers that have concerns regarding biotechnology-derived crops may use isolation and prudent bee management strategies to help mitigate cross-pollination to external alfalfa.

## 1.4 Hazard Assessment of Biotechnology-derived Crops and Associated Technologies on Honey Bees

Before commercialization, biotechnology-derived crops, including glyphosate-tolerant (GT) alfalfa and other GT crops, undergo extensive testing and evaluation as part of an environmental assessment to determine if there are any potential environmental effects. In particular, potential effects on non-target organisms (NTO) are considered. These potential effects are addressed via a science-based tiered assessment approach (Mendelsohn et al., 2003; Romeis et al., 2006, 2008; USDA/APHIS, 1997; U.S. EPA, 2007). A key component of that process is a problem formulation step that defines protection endpoints and management goals from which risk hypotheses are developed to evaluate risk. For biotechnology-derived crops expressing the herbicide-tolerance trait, a petition must be submitted to USDA/APHIS that addresses effects on NTO among other relevant factors. In most cases, EPA must be provided with information to support an amendment to the relevant herbicide label demonstrating that application of the herbicide to the herbicide-tolerant crop will not cause unreasonable adverse effects on the environment. For biotechnology-derived crops expressing insecticidally active proteins (termed PIPs or Plant Incorporated Protectants by the U.S. EPA), extensive evaluation including testing for potential effects on NTOs such as the honey bee have been conducted. The results of those analyses show that there are no negative effects of PIP-containing crops or their expressed proteins on honey bees (Mendelsohn et al., 2003; O'Callaghan et al., 2005; OECD, 2007; Rose et al., 2007; U.S. EPA Biopesticides Registration Action Documents) or bumble bees (*Bombus* spp.) (Babendreier et al., 2008). A recent meta-analysis by Duan and coworkers concluded that there was no evidence for any negative effects from use of registered PIPs on honey bees (Duan et al., 2008). It should be noted that GT alfalfa does not contain a PIP.

## 1.5 EPSPS Protein Specificity and Mode of Action

The EPSPS (5-enolpyruvylshikimate-3-phosphate synthase (EPSPS: EC2.5.1.19)) family of enzymes is ubiquitous in plants and microorganisms and their properties have been extensively studied (Dill, 2005). EPSPS proteins catalyze the transfer of the enolpyruvyl group from phosphoenol pyruvate (PEP) to the 5-hydroxyl of shikimate-3-phosphate (S3P), thereby yielding inorganic phosphate and shikimic acid-3-phosphate (5-enolpyruvylshikimate-3-phosphate), the penultimate product of the shikimic acid pathway (Alibhai and Stallings, 2001; Dill, 2005). EPSPS enzymes have extreme substrate specificity and bind only PEP and glyphosate, an EPSPS inhibitor. Shikimic acid is a substrate for the biosynthesis of aromatic amino acids (Phe, Trp and Tyr) as well as many secondary metabolites, such as tetrahydrofolate, ubiquinone and vitamin K. The shikimate pathway and, hence, EPSPS proteins, are absent in mammals, fish, birds, reptiles and insects including bees (Alibhai and Stallings, 2001).

The *cp4 epsps* gene is an *epsps* homolog isolated from *Agrobacterium* sp. strain CP4, a common soil-borne bacterium, (Padgett et al., 1996a, b). The *cp4 epsps* gene encodes the CP4 EPSPS protein. The CP4 EPSPS protein expressed in glyphosate-tolerant plants is functionally identical to endogenous plant EPSPS enzymes with the exception that CP4 EPSPS naturally displays reduced affinity for glyphosate, the active ingredient in Roundup® agricultural herbicides (Padgett et al., 1996a, b). In conventionally bred plants, glyphosate binds to the endogenous

plant EPSPS enzyme and blocks the biosynthesis of 5-hydroxyl of shikimate-3-phosphate, thereby starving plants of essential amino acids and secondary metabolites (Steinrücken and Amrhein, 1980; Haslam, 1993). In GT plants, the production of aromatic amino acids and other metabolites that are necessary for normal growth and development are met by the continued action of the glyphosate-tolerant CP4 EPSPS enzyme (Padgett et al., 1996a, b; Cerdeira and Duke, 2006, 2007). This difference in the glyphosate binding affinity is the basis for glyphosate tolerance in crops that produce CP4 EPSPS (Franz et al., 1997).

## 1.6 Safety Assessment of CP4 EPSPS on Arthropods

Safety assessments of GT crops, such as GT alfalfa, have shown that insertion of the *cp4 epsps* gene and the glyphosate-tolerant CP4 EPSPS protein does not alter the levels of nutrients and anti-nutrients in glyphosate treated and untreated plants (Heck et al., 2005; Nida et al., 1996; Padgett et al., 1996a; and Ridley et al., 2002; Nickson and Hammond, 2002; Cerdeira and Duke, 2006; U.S. FDA, 2008). For GT alfalfa, compositional analyses were performed for 35 nutritional components including proximates (protein, fat, ash and moisture), acid detergent fiber (ADF), neutral detergent fiber (NDF), amino acids, minerals, and carbohydrates (McCann et al., 2006; U.S. FDA, 2004). The values for all of the biochemical components assessed were similar to those of the conventional alfalfa grown in the trials or were within the range observed for conventional alfalfa. In addition, the levels of naturally occurring toxicants and anti-nutrients were addressed. Specifically, the levels of lignin (an anti-nutritional factor affecting digestibility), coumestrol (an estrogenically active phytoestrogen), as well as saponins and soluble forage proteins (both are associated with frothy bloat in ruminants), were all shown to fall within the ranges that occur in conventional alfalfa varieties (OECD, 2005). These data support substantial equivalence components of the risk assessment and establish that there should be no unintended effects of GT alfalfa, due to its equivalence with conventional alfalfa, on non-target organisms (Romeis et al., 2008).

Given the specificity of the EPSPS family of enzymes and their absence of demonstrated impacts in mammals, fish, birds, reptiles and insects (including bees), there is no known scientific basis to justify direct testing of this protein on specific non-target organisms such as bees (Cerdeira and Duke, 2006, 2007; Romeis et al., 2008). CP4 EPSPS containing crops, including alfalfa, canola, cotton, maize, and soybean have now been grown on many hundreds of thousands of hectares in excess of 10 years without any suggestion of negative effects on non-target organisms (Cerdeira and Duke, 2006; Dill et al., 2008). It may be noted that most of these crops serve as occasional nectar and or pollen sources for foraging honey bees. Even though the likelihood of hazard is low for the CP4 EPSPS protein, a number of researchers conducted laboratory and field investigations with different types of arthropods and other non-mammalian organisms exposed to GT crops containing the CP4 EPSPS protein, as discussed below.

Representatives of pollinators, soil organisms, beneficial arthropods and pest species were exposed to tissues from GT crops that contain the CP4 EPSPS protein<sup>52</sup>. These studies vary in design; some for relatively short duration and others for multiple generations (*Collembola*). Precise estimates of exposure of the test animals to the CP4 EPSPS protein in most of these test

---

<sup>52</sup> See document entitled "Food safety and environmental impact of the CP4 EPSPS protein.

systems were not assessed. Importantly, no toxicity was observed in arthropods exposed to these GT crops, reinforcing the conclusion of minimal hazard.

The risk assessment for CP4 EPSPS protein in GT crops reveals no evidence of unreasonable risk to NTOs because minimal hazard is predicted based on widespread occurrence of the EPSPS proteins and no scientifically plausible mechanism of toxicity. Although minimal ecological risk is predicted in the formal risk assessment process, several field-monitoring studies were conducted for GT crops to reinforce the conclusion and address any potential uncertainties in the risk assessment process. Plots were monitored for arthropod abundance in Roundup Ready 2 Corn, Roundup Ready Soybeans, Roundup Ready Sugar Beet and Roundup Ready Canola. Results of these studies are consistent with the predictions of the ecological risk assessment in that there is no evidence of unreasonable risk demonstrated in these studies. These results support the argument that the CP4 EPSPS expressed in GT crops such as GT alfalfa do not negatively affect non-target organisms such as honey bees.

## 1.7 Safety Assessment of Glyphosate on Arthropods

Glyphosate (N-(phosphonomethyl) glycine) is a non-selective systemic herbicide, first commercialized in 1974. Glyphosate herbicide is now one of the most widely used herbicides in the world (Franz et al. 1997; Giesy et al. 2000). Formulations of glyphosate have been extensively tested for a wide range of potential environmental effects and have proven safe for a wide range of organisms, including honey bees (extensively reviewed by Giesy et al., 2000 and see especially Agriculture Canada, 1991; U.S.EPA, 1993a; WHO, 1994). Regarding honey bees Giesey et al., 2000, states:

“Honey bees are not affected by glyphosate formulations, either by ingestion or direct overspray, at maximum use rates. The majority of other beneficial arthropods are unaffected by Roundup. Although screening tests under extreme exposure conditions indicate toxicity of glyphosate formulations to some beneficial arthropods, at the maximum use rates these effects were reduced or eliminated when more realistic exposure conditions were used. These data demonstrate minimal risk to beneficial arthropods in areas adjacent to treated fields. Within treated fields, vegetation changes resulting from herbicide use can lead to significant changes in beneficial arthropod populations.”

## 1.8 Exposure Assessment of Glyphosate-Tolerant Alfalfa and Honey Bees

### 1.8.1 *Exposure in Glyphosate-Tolerant Alfalfa Seed Production*

As of 2002, there were an estimated 2.4 million bee colonies in the U.S., of which the majority belong to commercial migratory (managed) beekeepers (Johnson, 2007). About one-third of these colonies are in California and Florida. Another 7% are found in the Dakotas and 5% are each located in Texas and Montana. Minnesota, Idaho, Michigan, Washington, Wisconsin, Oregon, and New York, collectively account for an additional 20%. Commercial migratory honey bee providers may move their hives two to five times per growing season. Estimates show that the majority of rented hives are used in apple and almond production, followed by

clover seed, cherry, and pear producers. Collectively, across all alfalfa cropping practices (seed and hay) it has been estimated that about 60% of all alfalfa pollinators are honey bees (Johnson, 2007; Morse and Calderone, 2000) but the number of acres with pollinating bees varies widely by crop purpose (seed vs. hay) and by geography. Therefore, the 60% estimate is not informative for the estimation of exposure since pollinators are not typical in hay crop production (99.5% of the U.S. alfalfa acres) and the choice of bee pollinator species in alfalfa seed production is highly dependent on geography and seed grower management.<sup>53</sup> A worst-case exposure estimate can be generated based on alfalfa seed production acreage (USDA-NASS, 2007) and typical pollinator species for the geography (CAST, 2008).

Forage Genetics International (FGI) is the sole seed-producing licensee of GT (Roundup Ready®) alfalfa (FGI, 2007, 2008). As such FGI contractually specifies which seed growers, field sites and under what protocols the GT alfalfa seed crop can be produced (i.e., licensed for variety increase). Of the growers in the eleven (11) western U.S. states that are eligible to grow GT alfalfa for seed<sup>54</sup>, only those in the Desert Southwest States (CA, AZ, etc.) rely predominately on commercially managed honey bees as pollinators. In other geographies where wild or commercial honey bees may be present (e.g. the Dakotas) GT alfalfa seed increase will either not be licensed<sup>2</sup> and/or seed producers stock non-*Apis* bee species. There are approximately 44,000 acres of alfalfa seed in the southwestern U.S., of which approximately 30,000 acres (CAST, 2008; McCaslin, 2007) is produced for export—this is a market sector that is sensitive to biotechnology-derived traits and unlikely to adopt GE varieties at this time (McCaslin, 2007; CAST, 2008). Therefore, only the domestic market acres (ca. 14,000 acres) under honey bee pollination are projected as likely candidates for licensed seed increase for GT alfalfa varieties. For exposure calculation purposes, 14,000 acres and 44,000 acres will be used as the likely and high acreage exposure estimates, respectively, and per Mueller (1989), the maximum hive stocking rate will be three colonies per acre. Using these data, the following worst-case exposure estimates were made (table O-1). These estimates show that the exposure of managed honey bee colonies to GT alfalfa seed production fields in the U.S. would range from 1.75% (projected) to potentially 5.50% (worst case) of the total managed honey bee population in a given year.

---

<sup>53</sup> Data cited by Johnson, 2007, reference Morse and Calderone, 2000. Morse and Calderone, 2000, provide a table entitled: "The Value of Honey Bees as Pollinators of U.S. Crops in 2000," that shows that for both seed and alfalfa hay production about 60% of all alfalfa pollinators are honey bees (Johnson, 2007; Morse and Calderone, 2000). While honey bees are used in the production of alfalfa seed, they are not used for alfalfa hay production. The attribution by the authors of 60% of the value of alfalfa hay to honey bees was meant to capture the indirect value honey bees contribute to the production of alfalfa hay and not to imply that honey bees are used or required for the production of hay once the grower has purchased alfalfa seed (Calderone, pers. comm.).

<sup>54</sup> FGI will limit the contracting of Roundup Ready alfalfa seed production acres to 11 western states--AZ, CA, CO, ID, MT, NV, OR, TX, UT, WA and WY, under terms of an industry coexistence consensus plan sponsored by The National Alfalfa & Forage Alliance (NAFA 2008). Seed production requires that Roundup agricultural herbicide be applied to the seed field. Such supplemental labeling is only available in these 11 states plus OK and NM where contracts have/will not be issued.

**Table O-1. Projected Likely and Highest (“Worst Case”) Exposure Estimates for Managed Honey Bee Colonies in Glyphosate-Tolerant Alfalfa Seed Production**

| Honey Bee Colonies in U.S. | Alfalfa Seed Production Acres, Total U.S. | Acres Pollinated by Honey Bees in Southwest U.S. | Acres Licensed for GT Alfalfa Seed Increase & Pollinated by Honey Bees | Colonies per Acre | Colonies Pollinating GT Alfalfa Seed Acres | Percent of Colonies Pollinating GT Alfalfa Seed Acres |
|----------------------------|-------------------------------------------|--------------------------------------------------|------------------------------------------------------------------------|-------------------|--------------------------------------------|-------------------------------------------------------|
| 2,400,000                  | 120,000                                   | 44,000                                           | Highest potential; all acres (44,000)                                  | 3                 | 132,000                                    | 5.50 %                                                |
| 2,400,000                  | 120,000                                   | 44,000                                           | Non-exported acres; likely potential (14,000)                          | 3                 | 42,000                                     | 1.75 %                                                |

## 1.9 Exposure in Honey Production

As stated above, although bees serve no direct agronomic (pollination) purpose in hay production fields, some alfalfa hay growers opt to allow their late-summer hay crop to flower extensively, precluding the harvest of maximum hay quality or yield. Working with honey bee keepers, these non-irrigated hay growers may allow their hay crop to flower and be used as an intentional source of honey bee forage instead of cutting for other livestock feeding purposes. In this situation, the bees are not “pollinators” used to produce the alfalfa crop *per se*; rather they are placed there as “foragers” to produce a honey crop and bee progeny (not seed).

While it is theoretically possible for exposure of honey-producing bees to GT alfalfa flowers found in fields where harvesting was delayed due to weather or on unmanaged feral plants to occur intermittently in some geographies, because of factors of scale, hay harvest routines and the seed purchase license restrictions, the extent and duration of any unintentional exposure is expected to be minor in comparison to intentional seed crop pollination use (see CAST, 2008; Kendrick et al., 2005). Hay growers that elect to plant GT alfalfa must sign a Technology/Stewardship Agreement that contractually obligates them to read and follow applicable sections of the Monsanto’s Technology Use Guide (TUG). For GT alfalfa, the TUG includes information on hay and forage management practices to promote high forage quality (i.e. before 10% bloom) and to prevent seed development.

Unintended exposure to GT alfalfa flowers can be further minimized by beekeepers if they opt to selectively place their hives near only conventional alfalfa variety fields rather than growers using GT alfalfa. The hay growers who purchase GT alfalfa will do so as a means to more efficiently produce high yielding, high quality forage alfalfa; these higher management alfalfa producers are unlikely to currently host bee hives because delayed harvest is incompatible with optimal forage harvest cycles. Such intensively managed pure-stand alfalfa is not needed by beekeepers and it is not optimal for fields used in honey production. Instead, honey producers

are more likely to work with a conventional alfalfa grower using marginal lands or lower inputs in geographies such as the upper plains states where extensive bloom is common (and geographically, growers are not eligible for GT seed production contracts). When alfalfa flowers are used as a source of nectar, the alfalfa may be grown mixed with clover. GT alfalfa varieties will not be grown in clover mixtures because clover is not glyphosate tolerant. Other flowers may also occur in the vicinity, decreasing the amount of foraging on alfalfa flowers. The majority of honey bees in a colony selectively collect nectar (not pollen) for honey production and only about 25% of honey bees actually forage for pollen (Arnett, 2002; Mueller, 1989). Because of the numerous biological and cultural mitigation factors, and the non-preference of alfalfa as a nectar source, exposure of honey bees outside of GT alfalfa seed producing areas is expected to be minimal.

Accurate estimates for the acreage of alfalfa devoted to honey production are not available, nor are there data for the number of pounds of alfalfa honey produced per year or the amount of honey produced per acre of alfalfa forage. Extension publications contain general references of “one-third of honey produced is from alfalfa” but verifiable numbers are not collected (Hannaway and Larson, 2004; Mulder, 2008). Honey production per acre of alfalfa is difficult to estimate since production is dependent on a number of abiotic and biotic factors including plant variety, geography, management practices and weather. However, a conservative worst-case estimate can be made by assuming that, if approximately one-third of the U.S. honey production is predominately alfalfa-based, then approximately one-third of honey bees are foraging predominately on alfalfa (table O-2). Therefore, of the 2.4 million colonies in the U.S. (Johnson, 2007), approximately 800,000 potentially forage on alfalfa. Using a stocking rate estimate of two to three colonies per acre (Mueller, 1989), then, it may be calculated that approximately 266,667 to 400,000 full-bloom alfalfa acres are used to support 800,000 colonies. The total acreage of alfalfa grown in the U.S. for hay and or seed production was nearly 24 million in 2007 (USDA, 2007). Therefore, approximately 1.2 to 1.8 percent of the total U.S. alfalfa (hay and seed) acreage is potentially used to support honey bee colonies during the longer days of summer when alfalfa has sufficient photoperiod to bloom and it remains unclipped.

As discussed above, due to the prohibitions in the Monsanto Technology Use Guide and the negative economic impacts of extensive flowering on forage quality and yield, optimally managed alfalfa hay fields (e.g., GT varieties) are very unlikely host fields for honey bee keepers. It is therefore likely that honey bees will only be intentionally placed on GT alfalfa when it is grown for seed increase (not forage), and then, only when the seed acres are planted in the irrigated desert valleys of California and Arizona where honey bees are the pollinator of first choice. In total, there are approximately 44,000 acres of alfalfa seed production in the Desert Southwest States (McCaslin, 2007; USDA, 2007) of which approximately 30,000 seed acres would be unlikely to plant GT alfalfa because they produce conventional seed for the export market (CAST, 2008; McCaslin, 2007). One possible conservative exposure scenario for honey production would be to assume that all of the remaining seed production acres in these southwestern geographies (i.e., ca. 14,000 acres) are planted to GT alfalfa seed production, honey bees are used as the sole pollinator species and honey is harvested. Under this scenario, the following conservative exposure estimates can be developed (table O-2):

- 0.06% of the total alfalfa acres in the U.S. would be GT *and* intentionally used to host honey bee colonies producing honey (i.e., 14,000 of 24 million acres);
- 3.5 to 5.3% of the current acres used to support alfalfa honey production acres (i.e., 14,000 of the 266,667 to 400,000 acres, overall) would encounter a change from conventional alfalfa flowers as bee forage to GT alfalfa flowers and all of these acres would be under seed producer variety increase contracts and license.
- Likewise, 3.5 to 5.3% of all U.S. alfalfa honey production would encounter a change from conventional alfalfa flowers as bee forage to GT alfalfa flowers and, essentially all of these bee keepers (and bees) would be working in close association as a pollinating service for a contracted, licensed GT alfalfa seed producer. Relative to this figure, only minimal additional exposure would be likely from delayed harvest forage fields or dispersed feral plants.
- 1.2 to 1.8% of all U.S. commercial honey bee colonies would be intentionally foraged on GT alfalfa flowers for the stocking rates of three and two colonies per acre on 14,000 acres, respectively (i.e., 28,000 to 42,000 of the 2.4 million bee colonies would be intentionally foraged on the GT alfalfa, inclusive of all hay and seed uses). Over 98 percent of cultured honey bee colonies would have little or no intentional foraging exposure to GT alfalfa.
- Assuming that one-third of this honey is sourced from alfalfa and exposure is estimated to be 1.2 to 1.8% of all honey bee colonies annually, a worst case estimate for honey sourced from GT alfalfa is 2.2% of the U.S. honey production.

**Table O-2. Post-Commercialization Exposure Estimates for the 2.4 Million U.S. Bee Colonies**

|                                                             | 3 colonies/acre |        | 2 colonies/acre |        |
|-------------------------------------------------------------|-----------------|--------|-----------------|--------|
| <b>Alfalfa acreage supporting honey bees (seed and hay)</b> | 266,667         |        | 400,000         |        |
| Acres of conventional alfalfa                               | 252,667         | 94.70% | 386,000         | 97.50% |
| Acres of GT alfalfa                                         | 14,000          | 5.30%  | 14,000          | 3.50%  |
| <b>Colonies supported by alfalfa flowers (seed and hay)</b> | 800,000         |        |                 |        |
| # colonies on GT alfalfa                                    | 42,000          | 5.30%  | 28,000          | 3.50%  |
| # colonies kept on conventional alfalfa                     | 758,000         | 94.70% | 772,000         | 97.50% |
| Estimated colonies kept on GT alfalfa flowers               | 42,000          | 1.80%  | 28,000          | 1.20%  |
| Estimated colonies kept on all other sources of flowers     | 2,358,000       | 98.20% | 2,372,000       | 98.80% |

### 1.10 Honey Bees and Colony Collapse Disorder

Honey bees are the major bee species used for crop pollination worldwide and in 2000 their contribution to U.S. agriculture, including alfalfa production, was valued at \$14.6 billion

(Greenleaf & Kremen, 2006). Currently, approximately 2.4 million managed honey bee colonies are used to pollinate crops in the U.S. (Johnson, 2007). This number represents a significant decrease from the estimated 4 million managed honey bee colonies present in 1981. This downward trend continues in both the U.S. and Europe. The National Research Council's (NRC) "Status of Pollinator's Committee" report (USDA-CCD, 2007) detailed the following problems facing the beekeeping industry including:

- Catastrophic problems with invasive parasitic mites (and resistance to pesticides meant to control them);
- Africanized honey bees which are aggressive and poor honey producers;
- The bacterial American foulbrood disease (and resistance to the antibiotic used to control it);
- The small hive beetle;
- A variety of viruses, bacteria, and fungi (including microsporidia);
- Insecticides with known toxicity to honey bees used in production agriculture; and
- Increased production costs and competition from cheap imported honey.

As listed above, honey bees face a number of abiotic and biotic stressors that can seriously disrupt or destroy a hive (Flottum, 2008a; MAAREC, 2007; USDA-CCD, 2007; Williams, 2008). Cultural practices by managed bee keepers can also potentially affect honey bee health. These include immune-suppressing stress from poor nutritional forage sources, apiary overcrowding, a lack of pollen or nectar, air pollution, drought, and migratory stress from long-distance transport of hives for pollination services (Endres, 2008; McFrederick et al., 2008; Williams, 2008). Crowding can also increase pathogen transmission. More recently Colony Collapse Disorder (CCD) has emerged (or possibly re-emerged) as a potential and poorly understood threat. Because of the importance of honey bees to U.S. agriculture, the U.S. Department of Agriculture (USDA) formed an ad hoc CCD Working Team comprised of academic, private, and Federal scientists to determine causes contributing to, and potential mitigation plans for, CCD (USDA-CCD, 2007).

CCD describes a phenomenon first reported in the U.S. in 2006-2007 in which honey bee colonies (*A. mellifera*) apparently disappear without a trace. A similar phenomenon has been observed in Europe (Belgium, Canada, France, the Netherlands, Germany, Greece, Italy, Portugal, Spain, Switzerland and the United Kingdom, West Africa, and Taiwan (Dupont, 2007; Flottum, 2008c; Kievits, 2007; Molga, 2007; Steinberger 2007). Large scale disappearances of honey bees are not new and are recorded as far back as 950 and 992 in Ireland, and more recently in the U.S. in the 1880s, the 1920s and the 1960s (Oldroyd, 2007). Isolated disappearances occurred in the Cache Valley of Utah in 1903 and in Pennsylvania in 1995-1996 (USDA-CCD, 2007). These disappearances have been variously named autumn collapse, disappearing disease, fall dwindle disease, May disease, and spring dwindle (Oldroyd, 2007). It is unknown whether these losses were related to the causal agent(s) of CCD or to some other stressor(s). Some experts argue, for example, that the case definition for CCD is ambiguous and that CCD may not be a new disorder because the symptoms for CCD are indistinguishable from those of other the normal diseases, such as winter colony collapse (Anderson and East, 2008; see also Oldroyd, 2007). At this time, however, most experts are classifying CCD as a unique disease (USDA-CCD, 2007) the symptoms of which include:

- Sudden loss of the colony's adult bee population with very few bees found near the dead colonies;
- Several frames with healthy, capped brood and low levels of parasitic mites which indicates that colonies were relatively strong shortly before the loss of adult bees and that the losses cannot be attributed to a recent infestation of mites;
- Food reserves that have not been robbed, despite active colonies in the same area, suggesting avoidance of the dead colony by other bees;
- Minimal evidence of wax moth or small hive beetle damage; and
- A laying queen often present with a small cluster of newly emerged attendants.

Some scientists believe that these symptoms are consistent with a disease or disease/pathogen interaction, perhaps aggravated by other sub-optimal cultural practices (CCD-USDA, 2007; Flottum, 2008a, 2008b, 2008d; Cox-Foster, 2008; Williams, 2008). Leading candidates are *Nosema* infections, mites and viruses.

*Nosema apis* and *Nosema ceranae* are microsporidian diseases of the western (*A. mellifera*) and eastern honey bee (*A. cerana*), respectively (Klee et al., 2007). In 2007, Klee and co-workers confirmed the presence of virulent *N. ceranae* in the western honey bee, first in Spain and Taiwan, and now world wide. Colonies can be simultaneously infected with both *Nosema* species. Symptoms of *Nosema* infection can be somewhat non-specific and thus confused with other diseases. They generally involve diarrhea and loss of female workers, which appear to be the most susceptible. *Nosema* infection shortens worker lifespan and can seriously weaken the colony leading to loss of hives.

Mite infestations of honey bees generally involve either the tracheal mite (*Acarapis woodi*) or the Varroa mite (*Varroa destructor*). A resistant strain of honey bee, as well as cultural controls, has been developed to control the tracheal mite. The Varroa mite is an obligate external parasite of both eastern and western honey bees (*A. cerana* and *A. mellifera*). Besides the visual presence of mites, other symptoms of mite infestation include the presence of dead bees in the hive and invasion of the hive by other pests as the hive weakens. Because mites feed on the hemolymph of bees and move between brood and adults, they are also capable of vectoring viruses such as the Deformed Wing Virus, a major pathogen affecting honey bee colonies (Lanzi et al., 2006).

A number of different viruses can infect honey bees (Chen et al, 2006). Many of the symptoms of CCD are consistent with a pathogen infection; therefore, viruses are likely candidates for the disease (Stokstad, 2007). For example, some investigators found that sanitation via irradiation of CCD affected combs allowed successful repopulation of the combs by honey bees (Williams et al., 2008). To try to identify a potential pathogen(s) as a causal agent of CCD, Cox-Foster and colleagues (2007) used an unbiased metagenomic approach to survey microflora in CCD hives, normal hives, and imported royal jelly. Their results showed a strong correlation of the incidence of CCD with the Israeli Acute Paralysis Virus (IAPV), which is either a new viral species or an unclassified virus possibly related to Kashmir bee virus (KBV) (Cox-Foster et al., 2007; Chen et al., 2007). IAPV is a single-stranded RNA virus in the family Dicistroviridae (genus *Iflavirus*) that can be vectored by the Varroa mite. IAPV is one of the top candidates as

the causal agent of CCD. Although the CCD Working Group is developing new recommendations regarding data collection to identify the cause of CCD, one conclusion reached very quickly for the CCD Working Group (USDA-CCD. 2007; MAAREC, 2007) was that:

*“Several other factors have been suggested as causal mechanisms of CCD, for example, the use of genetically modified (GMO) crops. However, large bee die-offs have also occurred in Europe, where GMO crops are not widely grown. Also, in the United States, the patterns of CCD-affected colonies do not appear to correlate with the distribution of GMO-crops such as Bt-corn. Furthermore, extensive laboratory and field testing has indicated a lack of acute and sub-lethal effects on bees exposed to GMO-pollen.”*

The CCD working group further stated that it is not currently investigating GMO crops because *“Some GMO crops, specifically Bt Corn, have been suggested as a potential cause of CCD. While this possibility has not been ruled out, CCD symptoms do not fit what would be expected in Bt affected organisms. For this reason GMO crops are not a “top” priority at the moment.”* (MAAREC, 2007)

## **2.0 Conclusion**

CCD is a serious threat to honey bee populations worldwide. Although the exact cause(s) of CCD is unknown, diseases and colony stress have been proposed as possible candidates. The temporal and geographic distribution of CCD, as well as the pathology associated with the disorder, are factors cited by the CCD working group. These factors limit the likelihood that any glyphosate-tolerant crop, including GT alfalfa, might be involved in CCD. A causal link between CCD and GT crops such as GT alfalfa is unlikely due to the limited exposure of honey bees to GT alfalfa and the lack of hazard associated with the CP4 EPSPS protein. In addition, the currently approved Bt crops referenced by the CCD working group occupy much of the same general agricultural acreage as GT crops, including the acreage that GT alfalfa is expected to occupy. Given the dynamics of GT alfalfa seed and forage production, the current worst case exposure estimates of commercial honey bee colonies to GT alfalfa flowers are 1.2 to 1.8%. Safety assessments and field observations, based on the mode of action of the CP4 EPSPS protein, suggest no potential negative effects on any animal including honey bees. Given the pathology and distribution of CCD and the lack of hazard or exposure of GT alfalfa to commercial honey bees, we conclude that there will be no negative impact on honey bees from the deregulation and commercial production of GT alfalfa.

## Biotechnology Consultation

### Note to the File

BNF No. 000084

**Date:** December 8, 2004

**Subject:** Glyphosate-tolerant (Roundup Ready®) Alfalfa Event J101 and Event J163

**Keywords:** alfalfa, *Medicago sativa* L., glyphosate (N-phosphonomethylglycine), glyphosate-tolerant, herbicide-tolerant, CP4 5-enolpyruvylshikimate-3-phosphate synthase (CP4 EPSPS), *Agrobacterium* sp. strain CP4, Roundup Ready®

### 1.0 Background

In a submission dated October 6, 2003, Monsanto Company (Monsanto) and Forage Genetics Incorporated (Forage Genetics) (jointly the notifiers) provided summary data and information supporting their safety assessment of two glyphosate-tolerant alfalfa (*Medicago sativa* L.) lines. One line contains the transformation event designated J101, and the second line contains the event designated J163. The notifiers intend to combine event J101 and event J163 through conventional breeding to produce commercial glyphosate-tolerant alfalfa seed. Monsanto and Forage Genetics submitted additional information in a submission dated June 15, 2004. Monsanto has successfully completed prior consultations with the agency on other glyphosate-tolerant plants expressing CP4 EPSPS protein.

### 2.0 Intended Effect

The intended effect of this genetic modification is to confer tolerance to the herbicide glyphosate, which is the active ingredient in Roundup®. The notifiers achieved this by transforming the parent alfalfa R2336 with a 5-enolpyruvylshikimate-3-phosphate synthase gene (*cp4 epsps*) from *Agrobacterium* sp. CP4 strain. The 5-enolpyruvylshikimate-3-phosphate synthase protein (CP4 EPSPS) encoded by this gene provides tolerance to glyphosate herbicide.

## 3.0 Method of Development

### 3.1 Genetic Modifications

Glyphosate-tolerant alfalfa events J101 and J163 were generated by *Agrobacterium*-mediated transformation of *Medicago sativa* L. line R2336 callus with the binary T-DNA vector PV-MSHT4. Transformant cells were identified through selection for glyphosate tolerance. The T-DNA segment of the PV-MSHT4 vector contains a single *cp4 epsps* expression cassette with the following elements intended for transfer to the recipient plant line during transformation.

| Name             | Description                                                                                         |
|------------------|-----------------------------------------------------------------------------------------------------|
| RB               | Right border                                                                                        |
| P-eFMV           | 35S promoter of the Figwort Mosaic Virus with duplicated enhancer region                            |
| HSP70-Leader     | The petunia heat shock protein 70 5' untranslated leader sequence                                   |
| CTP2             | Chloroplast transit peptide coding sequence derived from the <i>Arabidopsis thaliana epsps</i> gene |
| <i>cp4 epsps</i> | <i>cp4 epsps</i> gene derived from <i>Agrobacterium</i> sp. strain CP4                              |
| E9 3'            | Terminator sequence from the pea ribulose-1,5-bisphosphate carboxylase, small subunit E9 gene       |
| LB               | Left border                                                                                         |

The transformation vector PV-MSHT4 contains the *ori-322* origin of DNA replication, which allows the replication of the vector in the intermediate host *E. coli*, and the streptomycin adenyltransferase (*aad*) gene, which encodes a protein conferring resistance to the antibiotics streptomycin and spectinomycin. The *ori-322* and *aad* genes are located on the vector backbone, outside of the T-DNA border sequences; therefore, the genes are not intended for transfer to the recipient plant line during transformation.

### 3.2 Insert Characterization and Stability

The notifiers characterized events J101 and J163 using restriction endonuclease digestion and Southern blot analysis. According to the notifiers, the results of their characterization support the conclusion that, for events J101 and J163, a single, intact copy of the *cp4 epsps* gene cassette (of the PV-MSHT4 vector T-DNA) was incorporated into *Medicago sativa* L. line R2336, and that, for each event, the *cp4 epsps* gene cassette was incorporated at a different locus. The notifiers also used Southern blot analysis to conclude that the integrity of the *cp4 epsps* gene cassette was maintained and that alfalfa events J101 and J163 do not contain any detectable backbone sequence from the PV-MSHT4 vector.

2.1 The notifiers assessed the genetic stability of the insertions in J101, in J163, and in a population resulting from the conventional breeding of J101 and J163 (dihomogenic

population). The notifiers explained that, for the single event populations, both chi square analysis of phenotype segregation and Southern blot analysis of genotype segregation indicate a stable, one-locus Mendelian inheritance pattern and that, for the dihomogenic populations, chi square analysis of the Syn1 generation indicates normal Mendelian inheritance for the two independent loci.

The notifiers stated that alfalfa is an outcrossing autotetraploid plant with eight sets of chromosomes and that varieties of alfalfa are composed of a heterogeneous group of individuals. As a consequence of the genetics associated with conventional breeding of the J101 and J163 alfalfa lines, the *cp4 epsps* gene copy number is variable with advancing generations, ranging from zero to eight, for populations carrying both events.

## **4.0 Introduced Protein**

### **4.1 Identity and Function**

The expressed gene product in events J101 and J163 is a protein, CP4 EPSPS, derived from *Agrobacterium* sp. strain CP4. It is a single polypeptide 455 amino acids long and structurally and functionally similar to native plant EPSPS enzymes. Naturally occurring plant EPSPS, which catalyzes an essential step in aromatic amine synthesis essential to plant viability, is inhibited by the herbicide glyphosate. Compared to alfalfa EPSPS, the CP4 EPSPS protein has a much lower affinity for glyphosate, the active component of Roundup herbicide. Consequently, plant cells producing CP4 EPSPS are tolerant to glyphosate treatment.

The notifiers purified the CP4 EPSPS protein from the forage tissue of alfalfa plants containing either event J101 or event J163 and characterized the introduced protein using N-terminal sequence analysis, matrix assisted laser desorption ionization time of flight (MALDI-TOF) mass spectrometry, sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), Western blot analysis, and glycosylation analysis.

### **4.2 Expression Level**

The notifiers estimated the expression level of the CP4 EPSPS protein in J101 and in J163 by enzyme-linked immunosorbent assay (ELISA). They determined that the mean levels of CP4 EPSPS protein in forage from alfalfa plants containing event J101 and plants containing event J163, collected across two seasons and from six field sites, were 257 and 270 g/g of tissue fresh weight (tfw), respectively.

## **5.0 Safety Assessment of the Introduced Protein**

The notifiers presented data and information to support the safety of the CP4 EPSPS protein for human and animal consumption. They provided the following arguments in support of CP4 EPSPS protein safety:

*Agrobacterium* species are not known for human or animal pathogenicity; *Agrobacterium* sp. *cp4 epsps* has a history of use as a genetic donor in numerous glyphosate-tolerant crops, which humans and animals have consumed since 1996.

The CP4 EPSPS protein is functionally equivalent to native plant EPSPS protein except for its affinity for glyphosate.

Based on an amino acid homology search of several toxin databases, the CP4 EPSPS protein does not have biologically relevant structural similarities to protein toxins known to cause adverse health effects in humans or animals.

CP4 EPSPS protein is present at low levels: it represents only a relatively small portion of the total protein (0.49 percent in J101 and 0.52 percent in J163) in alfalfa. Fresh alfalfa forage contains 5.2 percent total protein levels and dried alfalfa contains approximately 20 percent protein by weight.

No treatment-related adverse effects were observed in an acute toxicity test in which mice were gavaged with doses of up to 572 milligrams of CP4 EPSPS1 per kilogram of body weight. According to the notifiers, this represents a safety factor for cows of approximately 26 and 27, for J101 and for J163 respectively, given a 630 kg cow consuming 13 kg of alfalfa dry matter per day.

The notifiers also assessed the allergenic potential for CP4 EPSPS protein produced from events J101 and J163. They concluded that the CP4 EPSPS protein from glyphosate-tolerant alfalfa lines J101 and J163 does not pose a significant allergenic risk based on 1) the absence of known reports of allergies to *Agrobacterium* species, which is the source of the *cp4 epsps* coding sequence transferred to the recipient plant lines, 2) the absence of immunologically relevant sequences, as determined by comparison of the amino acid sequence of the CP4 EPSPS protein to sequences in several allergen databases, and 3) the susceptibility of CP4 EPSPS protein to rapid proteolytic digestion in simulated gastric fluid.

## **6.0 Compositional Assessment**

The notifier states that alfalfa has a long history as a feed source for many animal species, but its greatest use is for dairy and beef cattle. Greater than 95 percent of alfalfa is used as animal feed on farms and is consumed as pasture, greenchop, silage, or dried forage. A small amount of alfalfa is sold and fed as dehydrated pellets. Human food uses of alfalfa are minor and are consumed as compressed leaf material for dietary supplements and herbal teas or as fresh sprouts.

### **6.1 Justification of Comparable Lines**

In their submission, the notifiers stated that, because alfalfa is an outcrossing autotetraploid, seed generated through self-pollination of a single genotype of alfalfa is not of adequate vigor for use in safety assessment studies. Consequently, they used a control population of null segregants (segregants lacking both the glyphosate-tolerant phenotype and the *cp4 epsps* genotype) from the

transformation protocol. The notifiers described how these "near isogenic" null segregants were developed in parallel with J101 and J163 and, in turn, were used to develop control alfalfa populations for use in compositional equivalence evaluations. Statistically significant differences between the transgenic and control alfalfa populations were declared at the 5 percent level of significance (i.e., where the p-value is less than 0.05).

## 6.2 Compositional Analysis

The notifiers compared the composition of simplex (single copy, single event) glyphosate-tolerant alfalfa lines J101 and J163 to the null segregant control line, using second cutting forage samples grown at five replicated field sites across the alfalfa-producing regions of the United States and harvested at the early to late bloom stage. A randomized complete block design with four blocks at each location was used. Twelve commercially available conventional alfalfa varieties, used to establish commercial compositional ranges, were grown at these sites, with four varieties grown at each of the five field sites. Forage samples were analyzed for 35 nutritional components including proximates (protein, fat, ash and moisture), acid detergent fiber (ADF), neutral detergent fiber (NDF), amino acids, various minerals and carbohydrates (by calculation).

The notifiers developed a tolerance interval using twelve different varieties of commercially available, conventional alfalfa to establish comparable ranges for compositional constituents. Using these ranges, the notifiers calculated the tolerance interval to contain, with 95 percent confidence, 99 percent of the values contained in the population of commercial alfalfa varieties. The notifiers used this 99 percent tolerance interval to determine if the test range was within the variance of a population of reference alfalfa varieties.

The notifiers stated that statistically significant differences were observed for the level of some analytes in comparison to the control population. For line J101, the mean level of cystine was greater than, and the mean levels of glutamic acid and tyrosine were less than, the null segregant controls. For line J163, the mean levels of cystine, acid detergent fiber (ADF), and neutral detergent fiber (NDF) were greater than, and the mean levels of histidine, lysine, and tyrosine were less than, the null segregant controls. However, the notifiers further noted that while the analyte levels were different, these levels were still within Monsanto's and Forage Genetics' commercial compositional ranges and their tolerance interval derived from data on conventional species grown at the same sites, and comparable to published literature values. The notifiers stated that the mean levels of iron and ash for the control and all varieties were unusually high but that these high mean levels could be attributed to high levels measured at one site. Consequently, repeat measurements were made for iron and ash the following year, resulting in levels similar to other sites and values found in the literature. The notifiers also found several differences in the level of nutrients within the locations, but except for the nutrients already cited, these were not consistent across locations. The notifiers therefore, concluded that these differences are unlikely to be biologically meaningful.

### 6.3 Levels of Naturally Occurring Toxicants and Anti-nutrients

The notifiers cited lignin, an insoluble amorphous macromolecule, as a key anti-nutritional factor in alfalfa where high lignin concentrations decrease alfalfa digestibility. The notifiers measured lignin levels in the forage of plants containing either event J101 or J163 as well as null segregant and commercial varieties. From these measurements, they concluded that the levels of lignin in J101-containing alfalfa were not statistically different from the levels of lignin in the control alfalfa population. The notifiers observed a statistically significant increase in the levels of lignin in J163-containing alfalfa when compared to the levels in control alfalfa. However, the notifiers noted that these levels were within their tolerance interval, established using data derived from conventional species and similar to published literature values. In summary, the notifiers concluded that the lignin levels in glyphosate-tolerant alfalfa are comparable to lignin levels in conventional alfalfa.

The notifiers reviewed the literature and concluded that coumestrol is the most estrogenically active phytoestrogen in alfalfa. The notifiers conducted field trials to measure coumestrol at four locations using a randomized complete block design with four replicates at each location. The combined statistical analysis of all the data showed no statistically significant differences. There were some location differences, but these were not consistent across all locations. The notifiers concluded that coumestrol levels in alfalfa lines J101 and J163 are equivalent to those in the null segregant controls and conventional alfalfa forage.

Digestive bloat constitutes a high health risk to cattle grazing on lush alfalfa pastures or fed fresh greenchop alfalfa. Saponins and soluble forage proteins are suggested as contributing agents to frothy bloat (ruminal tympany) in ruminants. The notifier concluded that a search of the literature did not reveal evidence showing that these compounds are the causative agents for bloat. Further, there are no reliable methods or databases on the level of saponins and soluble forage proteins in alfalfa.

In conclusion of their assessment, the notifiers state that alfalfa event J101 and event J163, and the feeds and foods derived from them, are as safe and nutritious as current commercial varieties of alfalfa and the comparable feeds and foods derived from them.

## 7.0 Conclusions

Monsanto and Forage Genetics have concluded that their glyphosate-tolerant alfalfa event J101 and event J163, and the feeds and foods derived from them, are not materially different in safety, composition, or any other relevant parameter from alfalfa now grown, marketed, and consumed. At this time, based on Monsanto's and Forage Genetics' description of its data and information, the Agency considers this consultation on alfalfa event J101 and event J163 to be complete.

<sup>(1)</sup>The CP4 EPSPS protein used in this study was produced in *E. coli*. Monsanto and Forage Genetics note that the CP4 EPSPS protein produced in *E. coli* is biologically, chemically, and functionally equivalent to the CP4 EPSPS protein produced in plants.

**Appendix Q.      Presence of Glyphosate-Tolerant  
Alfalfa in Human Food and Animal  
Feed**

# Presence of Glyphosate-Tolerant Alfalfa in Human Food and Animal Feed

## Executive Summary

Alfalfa (*Medicago sativa*) is the fourth most widely grown and third most valuable forage crop cultivated in the United States. This insect (bee) pollinated crop generally has a high yield, high protein and low fiber content, making it an ideal livestock feed (primarily dairy cattle and horse, but also used for beef cattle, sheep, and goats). Alfalfa is also consumed by humans as sprouts, herbal supplements or teas; the consumption in humans is smaller than that observed in livestock. In 2004, Monsanto Company and Forage Genetics International (FGI), jointly developed glyphosate-tolerant (GT) alfalfa, designated as events J101 and J163 that were genetically engineered for tolerance to the herbicide glyphosate (Roundup®). Since alfalfa is a very important forage crop, introduction of the GT variety for commercialization could lead to transgenic genes or proteins being present in organic or conventional alfalfa; thus warranting a thorough assessment of the potential impacts. This report examines scenarios where GT alfalfa may be found in animal feed and human food and addresses the potential human and livestock health implications of the same.

Glyphosate tolerance in alfalfa is achieved by genetically altering the alfalfa crop to express the soil bacterium, *Agrobacterium* sp. CP4 strain EPSPS (5-enolpyruvylshikimate-3-phosphate synthase) protein. The *Agrobacterium* sp. CP4 strain *cp4 epsps* gene encodes the CP4 EPSPS protein enzyme that has a reduced affinity for glyphosate when compared to the native alfalfa EPSPS enzyme. Glyphosate herbicide functions by inhibiting expression of plant EPSPS that results in the prevention of synthesis of essential aromatic amino acids. However, the CP4 EPSPS protein in the genetically engineered alfalfa is not hindered by glyphosate application.

Alfalfa is a herbaceous, short-lived perennial forage crop species that is predominantly and entirely dependent upon bees for pollination, therefore, gene flow by pollination between different alfalfa fields is probable. This becomes an issue when a proportion of cultivated alfalfa is GT alfalfa, and growers of conventional alfalfa wish to prevent the presence of GT alfalfa in their seed stock and crops. Alfalfa production occurs mainly in the West and Northwest United States where it is cultivated primarily for hay (forage) or seed. Gene flow between and into seed fields is of higher concern than gene flow into hay fields. Pollination of alfalfa is highly dependent on the species of pollinator used (honey bee, alfalfa leafcutter bee, alkali bee). Flower availability, the number of bees, weather, season, time of day, hive placement, plant competition, strength of the colony and disease are some of the other important factors that can potentially impact pollen transport. Feral alfalfa near seed fields can be an additional source of pollen and potential for gene flow if not contained adequately. However, proper adherence to FGI Best Practices and Monsanto's Monsanto Technology/Stewardship Agreement (MTA) has shown the risk of GT alfalfa presence to be well below FGI's goal of less than 0.5 percent unintended presence. Most countries importing organic alfalfa from the United States have a goal of no more than 1.0 percent.

The potential use of the GT crop and the associated use patterns of the herbicide glyphosate, the CP4 EPSPS gene and protein, the *Agrobacterium* utilized in creating GT alfalfa, and the herbicide itself were considered potential issues of concern and have been subsequently investigated. It should be noted at this point that Monsanto, the manufacturer of GT alfalfa does not allow GT alfalfa to be planted for sprouts (Hubbard, 2008); therefore, human direct consumption exposure to GT alfalfa appears to be minimal.

The U.S. FDA in 2004 conducted a safety assessment of the gene product and CP4 EPSPS protein to which the Agency concluded that the soil bacterium used to create GT alfalfa was not an allergen or pathogen and that the CP4 EPSPS gene and protein lacked structural similarities to any known allergens to humans. In humans, CP4 EPSPS protein has been shown to be readily degraded by digestive juices and has been evaluated by researchers to be non-toxic to mice when consumed at dose levels thousands of times higher than the expected human exposure. In addition, the CP4 EPSPS protein has been assessed previously for safety in approved genetically engineered lines that are readily consumed by humans such as canola, soybean, and corn and demonstrated little or no potential for toxicity in humans or animals. In 1996, GT soybeans were deregulated and no adverse health events have been reported for it or other GT food crops. Studies on the persistence of plant-derived recombinant DNA in livestock have indicated that feed ingested DNA fragments do survive in the terminal gastrointestinal (GI) tract and that uptake into the gut epithelium does occur. There is no evidence thus far to indicate that the recombinant DNA would be processed in a manner any different from the endogenous feed-ingested genetic material. Additionally, no deleterious effects of CP4 EPSPS protein or gene consumption by dairy cattle, livestock, or poultry nutritional parameters have been reported. Field observations of events J101 and J163 have revealed no negative effects of the transgene on non-target organisms such as bees and earthworms. No effects have been observed on pollen harvest behavior of worker bees, or on survival and development of honey bee eggs, larvae or pupa post exposure to the CP4 EPSPS protein.

One of the potential outcomes of commercializing GT alfalfa would be increased usage of the herbicide glyphosate. Glyphosate tends to adsorb strongly to soil particles and residues are not expected to leach into groundwater. Monitoring studies indicate that glyphosate and its primary metabolite amino methyl phosphonic acid (AMPA) are more likely to exist in surface waters in the vicinity of agricultural applications. The risk to human and animal health from glyphosate exposure depends on both the toxicity of the glyphosate and the likelihood of people or organisms coming into contact with the herbicide. Humans and animals can be exposed to glyphosate via one of three potential exposure routes: inhalation, dermal, and oral (ingestion). Considering the nature of glyphosate application, farm workers who spray the pesticide may be at most risk of exposure to glyphosate. A bio-monitoring study of pesticide applicators conducted in 2004 indicated that the highest estimated bodily adsorption of glyphosate in farm workers was 400 times less than the Reference Dose (RfD) established for glyphosate. The Reference Dose, established to be 2 mg/kg/day, is the safe level of glyphosate that can be consumed everyday for a lifetime in a human. This same study also indicated that people in the vicinity of farming operations, but not directly involved in glyphosate spraying operations had little detectable exposure to glyphosate (2,500 times less than RfD for children and 50,000 times less than RfD for spouses of farm workers). Considering the similarity of the glyphosate use

pattern and application rates in this study compared to those registered for use on GT alfalfa, bystander exposure attributed to the use of glyphosate on glyphosate-tolerant crops is expected to be negligible.

The toxicological review of the glyphosate herbicide indicates that it does not appear to result in adverse effects on development, reproduction, or endocrine systems in humans and other mammals. Under present and expected conditions of use, glyphosate herbicide does not seem to pose a health risk to humans. There is little evidence of any direct effect of glyphosate on arthropods in the field or in natural environments and the higher toxicity of glyphosate observed in aquatic invertebrates can mainly be attributed to the presence of surfactants used to make glyphosate herbicide products penetrate the leaf cuticle.

The CP4 EPSPS gene and protein, the *Agrobacterium* utilized in creating GT alfalfa and the herbicide glyphosate have been shown to be non hazardous to humans, livestock and non-target animals. The potential for food exposure in humans is considered negligible and concerns of exposure in non food scenarios were mitigated using data from bio-monitoring studies. There is little evidence that the gene, protein, or herbicide have any direct toxic effect on livestock or any deleterious outcome on nutritional parameters. Best Manufacturing Practices and Monsanto's (MTA) agreement are considered sufficient to alleviate concerns regarding cross-fertilization from GT to non-GT seed fields or from hay to seed fields. From the human food and animal feed viewpoint, commercializing of GT alfalfa does not pose a significant risk to human, livestock, and wildlife.

## 1.0 Introduction

The scope of this report covers how glyphosate-tolerant (GT) alfalfa could be present in human food and animal feed and the resulting health impacts of that presence.

Alfalfa an important forage crop in the U.S., farmers use alfalfa to feed their livestock (e.g., dairy cows, sheep, and goats). Alfalfa is an important animal feed because of its high protein and low fiber content. Alfalfa ranks fourth on the list of most widely grown crops, behind corn, soybeans, and wheat, and it is the third most valuable to agriculture. Alfalfa is consumed by humans as alfalfa sprouts, herbal supplement, or as tea; however, these are minor consumption categories comparatively to the amount used as animal forage.

### 1.1 Alfalfa Biology and Usage

Alfalfa (*Medicago sativa* L.) is a short-lived perennial herbaceous legume (Lesins and Lesins, 1979) and is exclusively an insect-pollinated crop that is pollinated by a small number of insect species, all of which are bees. A concise, recent review of several salient features of the biology of alfalfa within the context of gene flow was recently developed by an expert panel assembled by the National Alfalfa & Forage Alliance (Van Deynze et al., 2008), which is discussed in further detail in section 3 of this technical report.

Alfalfa grown for forage is the third-ranked crop in the U.S. by value and fourth ranked by total acreage. The number and location of alfalfa forage acres are closely associated with livestock operations, especially dairy. Alfalfa is highly valued for animal feed because of its high protein content, high intake potential, and digestibility. It can provide the sole plant component in many livestock feeding programs when supplemented with the proper minerals.

In the U.S., the vast majority of alfalfa is harvested as forage for use as animal feed; however, some minor food uses of alfalfa occur such as use of seed for sprout production and the production of dietary supplements or tea. In 2005, alfalfa dry hay produced in the U.S. was valued at over \$7.3 billion with 99 percent of it used on-farm or sold within the U.S. (USDA-NASS, 2006) for animal feed. Alfalfa hay export was valued at approximately \$192 million (USDA-FAS, 2006), representing roughly two percent of the total dry hay crop value. Of the domestic use total, less than one percent of alfalfa hay acres were harvested as organic in 2005 (USDA-NASS, 2006). Five countries (Japan, Republic of Korea, Taiwan, Canada and Mexico) account for 98 percent of the total metric tons exported. Japan imports 74 percent of the alfalfa exports from the U.S. and is consistently the largest annual importer of U.S. alfalfa hay.

### 1.2 Conventional Alfalfa Crop

Conventional alfalfa has been used for animal feed for decades. Alfalfa is also consumed minimally by humans (e.g., sprouts, dietary supplements, and herbal teas). Pollen from alfalfa may be a minor contributor to some respiratory allergic diseases such as asthma, but the risk to human health is minimal. In addition, alfalfa sprouts have been the source of several foodborne outbreaks due to bacterial contamination (US FDA, 1999). Epidemiological investigations suggest that seeds are the likely source in most, if not all, sprout-associated illness outbreaks. Seeds grown for sprouts have more stringent restrictions for chemical applications during

growing since the chemicals must be evaluated as food residues. FDA considers GT alfalfa not materially different from conventional alfalfa; therefore it is permitted for human consumption (US FDA, 2004a). However, Monsanto does not allow GT alfalfa to be planted for sprouts (Hubbard, 2008).

### 1.3 Gene and Gene Product

Production of a genetically engineered (GE) organism involves integration of a novel DNA sequence into the plant's genomic DNA, called a transformation event. The novel DNA construct contains all the genetic information needed to produce the new characteristic or trait and, in most instances, this includes production of a novel protein. The expressed gene product in Roundup Ready® alfalfa is a protein, 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS), derived from a soil bacterium, *Agrobacterium* sp. CP4 strain, thus called CP4 EPSPS. The protein is a single polypeptide that is 455 amino acids long and structurally and functionally similar to the native plant EPSPS enzymes. The herbicide glyphosate inhibits an essential step in aromatic amine synthesis in plants. The CP4 EPSPS protein is not inhibited by the herbicide glyphosate; thus any plant with the protein is resistant to glyphosate application.

The U.S. Food and Drug Administration (FDA), the lead U.S. regulatory agency for review of the food and feed safety of GE crops, completed a voluntary consultation with FGI and Monsanto in 2004 regarding the safety of GT alfalfa (US FDA, 2004b). The FDA made the following assertions: the soil bacterium used to create GT alfalfa is not a known allergen or pathogen; the CP4 EPSPS gene and protein lack structural similarities to any allergen; the CP4 EPSPS protein is only a small portion of alfalfa; and while acute toxicity in mice was observed, allergenic responses associated with Roundup Ready® crops have not been reported by farm workers or members of the general population since the commercialization of these crops in 1996. FDA (2004b) did not review studies on dermal or inhalation toxicity of the CP4 EPSPS gene or protein, nor were any available at the time of this analysis.

### 1.4 Herbicides

There are several herbicide products containing glyphosate that are recommended for use on GT alfalfa. These products include: Roundup Original Max®, Roundup Weather Max®, and Roundup Ultra Max II® (Monsanto, 2008). According to Greenbook, an online database that partners with chemical manufacturers such as Monsanto to provide information about agricultural products, Honcho® and Honcho Plus® are also recommended for use on GT alfalfa (Greenbook, 2008). Each of these products contains between 41 and 48 percent glyphosate (Monsanto, 2004; 2007b; 2007d; 2007e; 2007f).

The adoption of GT crops has caused a shift in herbicide usage; generally glyphosate usage has increased while other herbicides have declined resulting in a reduction in total herbicide usage. Several reviews concerning GE crops and herbicide use have supported this conclusion (Brimner et al., 2005; Fernandez-Cornejo, 2006; Gianessi and Reigner, 2006; Kleter et. al., 2007; Sankula, 2006; Johnson et al., 2008). However, in 2004, Charles M. Benbrook asserted that herbicide usage increased based due to the adoption of herbicide-tolerant crops. The data set used to

determine these trends in herbicide usage were from USDA's National Agricultural Statistics Service (NASS), which is not comprehensive and the data differs yearly as to what is reported. For example, different states report glyphosate use from year to year for corn or soybeans. This discrepancy in reporting and data collection causes controversy over the exact amount of national use of herbicides. However, all analyses agreed that the herbicide glyphosate usage increased due to the adoption of GT crop technologies. GT alfalfa is cultivated almost identically to conventional alfalfa except for the use of glyphosate during post emergence.

Bio-monitoring studies confirm that agricultural workers who apply glyphosate to crops internalize some of the chemical (Curwin et al., 2007; Mandel et al., 2005). EPA (1993) determined in its RED for glyphosate that the chemical may be classified as either a Category III (i.e., slightly toxic; slightly irritating) or Category IV (i.e., practically non-toxic; not an irritant) toxicant. Toxicity and occupational exposure data exist for glyphosate, and this assessment utilizes these data to estimate exposure and risk to field workers.

## 1.5 Methodology

A literature search was designed to identify peer review articles and grey literature (e.g., government reports, State Agricultural Extension Office publications) on GT alfalfa and gene flow, toxicity, and occurrence in food or livestock feed (appendix A). Several DIALOG databases were searched. Google and Google Scholar search engines supplemented the DIALOG search. Alfalfa harvest statistics were obtained from USDA's National Agricultural Statistics Service (<http://www.nass.usda.gov/index.asp>). In addition, USDA's Economics, Statistics and Market Information System (ESMIS), which is a collaborative project between Albert R. Mann Library at Cornell University and USDA, provided information on alfalfa harvesting (<http://usda.mannlib.cornell.edu/MannUsda/homepage.do>). USDA's Agricultural Marketing Service also provided information on harvests (<http://www.ams.usda.gov>).

## 2.0 Glyphosate-Tolerant Alfalfa Hazard Identification

Alfalfa (*Medicago sativa* L.) is a perennial herbaceous legume pollinated by bees and cultivated primarily as forage for use as animal feed. Alfalfa is an important animal feed because of its high protein and low fiber content, and is a staple of most livestock diets, especially dairy cows (Martin et al., 2005). Monsanto Company and Forage Genetics International, jointly developed GT alfalfa, designated as events J101 and J163 that were genetically engineered for tolerance to the herbicide glyphosate (Roundup). The possibility of these genetically engineered varieties being present in food and feed supplies and the importance of the alfalfa crop, warrant a thorough assessment of the impacts, if any, of introducing the GT alfalfa crop for commercialization.

### 2.1 Glyphosate-Tolerant Alfalfa Biology

Glyphosate-tolerance in alfalfa was developed using *Agrobacterium*-mediated transformation to incorporate into the alfalfa genome the *cp4 epsps* coding sequence that produces a glyphosate-tolerant form of EPSPS. The protein is a single polypeptide that is 455 amino acids long and structurally and functionally similar to the native plant EPSPS enzymes. The enzyme 5-enolpyruvyl-shikimate-3-phosphate synthase (EPSPS) is inhibited by glyphosate, which prevents the plant from synthesizing the aromatic amino acids phenylalanine, tyrosine, and tryptophan. The CP4 EPSPS protein is not inhibited by the herbicide glyphosate; thus any plant with the protein is resistant to glyphosate application. Several studies have shown that conventional and GT alfalfa are compositionally and nutritionally similar, please refer to technical report *Character and Quality of Glyphosate Alfalfa Traits* (appendix U) for further details. Compositional analyses of the forage samples included proximates (protein, fat, ash and moisture), acid detergent fiber (ADF), neutral detergent fiber (NDF), lignin, amino acids, and minerals (calcium, copper, iron, magnesium, manganese, phosphorous, potassium, sodium and zinc), as well as carbohydrates by calculation. Reviews on the nutritional quality of GE foods conclude there's no significant nutritional difference in conventional versus GE plants for food or animal feed (Flachowsky et al., 2005). Steckel and colleagues (2007) evaluated GT alfalfa for three years with glyphosate treatments ranging from 0.75 to 3 lbs a.e./acre for crop injury and feed quality. Levels up to 9 lb a.e./acre glyphosate over 3 years did not cause a reduction in yield or nutrition. The label rate for glyphosate application to GT alfalfa is no greater than 1.55 lb a.e./acre.

#### 2.1.1 CP4 EPSPS Gene and Protein Occurrence and Exposure

FDA considers GT alfalfa not materially different from conventional alfalfa (US FDA, 2004a). Monsanto does not intend to introduce GT alfalfa into the human food supply, either as compressed leaf material or as sprouts. GT alfalfa will be sold solely in the U.S. to producers of forage for use as animal feed.

##### 2.1.1.1 CP4 EPSPS Gene and Protein Detection Methods

After StarLink corn, a non-human food-use GE corn was found in the food supply, sampling and food surveillance was brought to public attention. Another incident was an accidental shipment of an unapproved GE corn variety for cultivation that occurred between 2001 and 2004 (Alexander et al., 2007). Labeling of products as not containing GE ingredients, such as those products having ‘GE-free’ claims, also bolsters the need for reliable and sensitive detection methods for GE food products. Methods for detecting GE materials range in their limits of detection. In many situations, a test will be required that not only detects the presence of GE material, but also measures the amount of GE content in the sample. All testing methodologies detect either the novel DNA or the novel protein. The major trait-specific or protein detection methods are immunoassays or Enzyme Linked Immunosorbent Assays (ELISAs), and make use of the properties of antibodies. ELISAs are easy to use, robust and cheaper than DNA detection methods but generally less sensitive (Griffiths et al., 2002). The most commonly used DNA amplification method is the Polymerase Chain Reaction (PCR), though there are other amplification methods to suit specific applications.

For each testing method, a Limit of Detection (LOD) is defined to show the sensitivity of the method. For example, a method with an LOD of 1 percent (w/w) for Roundup Ready® soy would be able to detect Roundup Ready® soy in a batch of soy flour when present as 1 percent (w/w) of the total soy flour (Griffiths et al., 2002). It is important to note that this LOD value written in an abbreviated form means the LOD for Roundup Ready® soy is 1 percent (w/w) of total soy flour if the product is comprised of 100 percent soy (Griffiths et al., 2002). For food products containing several ingredients, estimation of the LOD is less reliable. Using the previous example, if the 1 percent (w/w) GE soy flour were used as a baking ingredient in cake, the soy flour may make up only 0.5 percent (w/w) of the total cake ingredients. The GE soy would thus be only 0.005 percent (w/w) of the total sample, which would be well below the LOD for this method (Griffiths et al., 2002). The LOD is normally defined on a percent (w/w) basis, the actual measurement of GE ingredients is based on either DNA or protein and this DNA- or protein-based measurement is not necessarily directly transferable to a percent (w/w) measurement (Griffiths et al., 2002). Efforts are being made through various governments to develop reliable detection methods and monitoring plans. Labeling and traceability of GE foods has spurred the need for reliable detection methods (Alexander et al., 2007), discussed further in section 2.1.1.2. below. Some highly processed foods contain no traces of DNA and/or protein. In these cases, there is no analytical method available to identify whether these products are derived from GE materials.

#### 2.1.1.2 Labeling Standards

The United States does not require labeling of GE products. It is the responsibility of the producer/farmer to verify the absence or presence of GE material if needed through a contractual obligation, and/or to ensure that levels of GE material meet tolerance levels established by an end user. The default standard for certification as GE free has been taken to be zero percent in many cases, although experience shows that meeting such a standard is difficult. There have been proposals for setting maximum allowable levels in the range of 1 to 3 percent (Thomison and Loux, no date).

The labeling legislation is not well harmonized internationally (Griffiths et al., 2002). Whilst Australia has a tolerance level of 1 percent unintended GE material, other countries such as

Japan and Korea currently have a higher tolerance level of 5 percent (Griffiths et al., 2002). The requirement for labeling in the USA is voluntary. On the other hand, the European Commission (EC), on behalf of the European Union (EU), has proposed new legislation to drop the threshold for the presence of unintended GE content from 1 percent to 0.5 percent. The EU is also planning to adopt a process-based rather than the product-based GE food labeling approach, so that any product derived from gene technology would have to be labeled, even if the novel DNA and/or protein were completely removed. The commercial feed producer is required by EU legislation to label feed containing GE feed ingredients. At present, European Market Regulations 2003/1829/EC and 2003/1830/EC govern the use of GE ingredients intended for food, feed, and food additives. Threshold labeling at 9 g/kg (0.9 percent) for the unintended presence of approved GE material and 5 g/kg for GE materials not approved in Europe is required (Bakke-McKellep et al., 2007). In addition, a 0.5 percent labeling threshold has been mandated for GE crops that have been given a favorable risk assessment but are not yet approved within the EU. Unapproved varieties are managed with zero tolerance (Alexander et al., 2007). Products such as milk, meat, and eggs, and that are derived from livestock fed transgenic feeds are exempt from EU-labeling laws. Currently, only the EU and Switzerland have labeling regulations pertaining to GE feed (ISAAA, 2005). Figure Q-1 below illustrates the countries with GE food labeling, thresholds, and date of regulation.

Regulations concerning the labeling of GM food or feed products in select countries<sup>a</sup>

| Country                   | Labeling status                              | Threshold (percent)                               | Date of implementing threshold regulation |
|---------------------------|----------------------------------------------|---------------------------------------------------|-------------------------------------------|
| Australia and New Zealand | Mandatory                                    | 1                                                 | December 2001                             |

| Switzerland               | Mandatory                                    | 2 or 3 (feed <sup>e</sup> ), 0.5 (imported seeds) | Not available                             |
| Taiwan                    | Mandatory                                    | 5                                                 | Proposal                                  |
| Thailand                  | Mandatory for selected products              | 5                                                 | Proposal                                  |
| United States             | Voluntary                                    |                                                   | January 2001                              |

Data have been converted to SI units.

<sup>a</sup> Data from Jia (2003) and ISAAA (2005).

<sup>b</sup> Labeling required if safety concerns (allergenic, change in nutritional composition) exist.

<sup>c</sup> Labeling required at a 0.9% threshold for approved GM organisms or 0.5% for GM organisms given a favorable risk assessment but not yet approved. Includes both feed and food products.

<sup>d</sup> Labeling required only if recombinant DNA or proteins are detected.

<sup>e</sup> Threshold for feeds containing raw material of a single source is 3%. For mixed feeds, a threshold of 2% exists.

Figure Q-1: Regulations on GE food labeling throughout the world (Alexander et al., 2007)

### 2.1.1.3 Detection in Food Products

There is some literature available on the detection and quantification of GE material in various foods. In an Australian monitoring study (Griffiths et al., 2002), the GT trait was detected in soy flour, soy protein isolate, soy milk, snack foods, biscuits, powdered bread, and corn flour as illustrated in figure Q-2 below.

| Round           | Number  | Test Material                            | Ingredient          | GM Ingredient <sup>a</sup> |                    |                   | Laboratory results |              |        |
|-----------------|---------|------------------------------------------|---------------------|----------------------------|--------------------|-------------------|--------------------|--------------|--------|
|                 |         |                                          |                     | GM Trait                   | % of GM Ingredient | % in Test Product | No. Results        | % of results |        |
|                 |         |                                          |                     |                            |                    |                   |                    | present      | absent |

### 2.1.1.4 Detection of CP4 EPSPS Gene or Protein in Downstream Animals

To date, no recombinant DNA sequences have been found in any organ or tissue sample from animals fed GE plants (Flachowsky et al., 2007). As described by the European Food Safety Authority (EFSA) in 2007 the fate of recombinant DNA from genetically engineered plants or resultant proteins are dependent on the following four factors:

- the fate of the recombinant DNA and protein during the feed processing and ensilaging;
- the fate of the recombinant DNA and protein in the gastrointestinal tract of animals fed with the GE feed;
- the potential absorption of the digested pieces of DNA or protein into animal tissues/products;
- and
- the potential of biological functionality of absorbed DNA and protein fragments.

No study has found that mechanical treatment (e.g. baling, chopping, processing) of animal feed has effect on DNA stability (EFSA, 2007). Digestion in the gut requires DNA and protein to be broken down to the building blocks of fragments and nucleotides; proteins into polypeptides, oligopeptides, and amino acids; the transformation DNA and protein are digested in similar manner to native DNA or proteins. This rapid breakdown in the stomach and upper portions of the small intestine minimizes the chance of adsorption of the transformed DNA or protein. From EFSA:

“In 2006, the Council for Agricultural Science and Technology (CAST) published a paper entitled “Safety of Meat, Milk, and Eggs from Animals Fed Crops Derived from Modern Biotechnology” (CAST, 2006). This report indicates that no intact or immunologically reactive fragments of recombinant plant proteins or DNA have been detected in samples of meat, milk, eggs, lymphocytes, blood, and organ tissue from production animals fed crops modified for agronomic traits using recombinant DNA technology.”

In field tests, CP4 EPSPS was found in GT soybean at 0.1 percent in chicken feed (Ash et al., 2003) by an ELISA method; no detectable amounts of CP4 EPSPS protein were in whole egg, egg albumen, liver, or feces of the chickens fed GT soybeans.

Conventional PCR/Southern Blot and an ELISA method were utilized to determine if transgenic DNA or protein were detectable in pigs fed GT soybeans (Jennings et al., 2003). The routine LOD for the present PCR/Southern blot detection of *cp4 epsps* and *le1* gene fragments was approximately 2.5 pg (extremely sensitive) of purified GT soybean genomic DNA per reaction. The CP4 EPSPS competitive immunoassay had an LOD of approximately 94 ng (1000 fold less sensitive than the PCR/Southern Blot, yet still sensitive) of CP4 EPSPS protein/g of pork loin tissue extract (~94 ppb). There was an absence of detectable levels of fragments of either transgenic DNA or protein, which confirms DNA and proteins undergo degradation in animal digestive tracts (Jennings et al., 2003).

Quantitative real-time PCR and conventional PCR was used to evaluate glyphosate-tolerant canola *cp4 epsps* transgene in the intestines, rumen, or feces of sheep feed canola meal (Alexander et al., 2004). Digestion of plant material and release of transgenic DNA can occur in the small intestine of sheep. The free transgenic DNA is rapidly degraded at neutral pH in small intestine duodenal fluid, thus reducing the likelihood that intact transgenic DNA would be available for absorption through the Peyer’s Patches further down in the distal ileum of the small intestine (Alexander et al., 2004).

The persistence of plant-derived recombinant DNA in sheep and pigs fed genetically engineered (GT) canola was assessed by Sharma et al. (2006) utilizing Polymerase Chain Reaction (PCR) and Southern hybridization analysis of DNA extracted from digesta, gastrointestinal (GI) tract tissues, and visceral organs. This study confirmed that feed-ingested DNA fragments (endogenous and transgenic) do survive to the terminal GI tract and that uptake into gut epithelial tissues does occur. A very low frequency of transmittance to visceral tissue was confirmed in pigs, but not in sheep. There was no evidence to suggest that recombinant DNA would be processed in the gut in any manner different from endogenous feed-ingested genetic material.

### 2.1.2 CP4 EPSPS Gene and Protein Toxicity

The U.S. Food and Drug Administration (FDA), the lead U.S. regulatory agency for review of the food and feed safety of genetically engineered crops, completed a voluntary consultation with FGI and Monsanto in 2004 regarding GT alfalfa (US FDA, 2004b). Specifically, FDA (2004b) made the following conclusions of the gene product, CP4 EPSPS:

the soil bacterium used to create GT alfalfa is not a known allergen or pathogen;  
the CP4 EPSPS gene and protein lack structural similarities to any allergen;  
the CP4 EPSPS protein is only a small portion of alfalfa; and while acute toxicity in mice was observed,  
allergenic responses associated with Roundup Ready® crops have not been reported by farm workers or members of the general population since the commercialization of these crops in 1996.

FDA (2004b) did not review studies on dermal or inhalation toxicity of the CP4 EPSPS gene or protein, nor were any available at the time of this analysis. Immunological response in Sprague-Dawley mice were negative after exposure to purified EPSPS protein (Chang et al., 2003)

## 2.2 Herbicide Glyphosate Use on GT Alfalfa

Glyphosate is among the most widely used pesticides by volume in the United States; glyphosate use data for GT alfalfa were only found for Monsanto products. The only end use herbicide products approved and that have a subsequent proposed maximum use rate for GT alfalfa are the following Monsanto glyphosate herbicide products: Honcho, Honcho Plus, Roundup Original MAX, Roundup WeatherMAX, and Roundup Ultra MAX II. Glyphosate products can be formulated to have different concentrations of glyphosate acid per gallon of product. To improve handling, performance, and concentration, the glyphosate acid is formulated as a salt compound. The term acid equivalent (a.e.) refers to the weight of the glyphosate acid, which is herbicidally active, while the term active ingredient (a.i.) is the weight of the glyphosate acid plus the salt. It is best to refer to a.e. when comparing glyphosate products and rates. For the quantitative ecological Tier 1 risk assessment (*Potential Impacts To Wildlife, Amphibians, Plants And Ecosystems From Increased Glyphosate And Other Chemical Usage*; appendix N), human health risk assessment (*Health And Safety Risks From Increased Glyphosate And Other Chemical Usage On Humans (Exclusive Of Field Workers)*; appendix L), and occupational health risk assessments (*Health And Safety Risks To Field Workers*; appendix M), the maximum use rate of 7.98 lbs a.e./acre year, with a single maximum use rate of 1.99 lb a.e./acre and a minimum reapplication rate of 7 days was used. The values used for this risk assessment are higher than the maximum label rate for glyphosate on GT alfalfa (maximum single use rate is 1.55 lbs a.e./acre, and maximum yearly rate 5.96 lbs a.e./acre for application of glyphosate to GT alfalfa). Each of the technical reports listed previously provide in depth detail on the toxicity, exposure, and quantitative risk assessment of glyphosate usage on GT alfalfa.

### 2.2.1 Glyphosate Occurrence and Exposure

#### 2.2.1.1 Glyphosate Overview of the Chemical Fate and Occurrence

Glyphosate adsorbs strongly to soil and is not expected to move vertically below the six inch soil layer; residues are expected to be immobile in soil (US EPA, 1993, 2006). Glyphosate is primarily degraded by soil microbes in the environment. The major degradate of this process is aminomethyl phosphonic acid (AMPA), which further degrades in the soil to carbon dioxide. The half-life of glyphosate in soil laboratory studies is two days (US EPA, 1993, 2006). In agricultural soils, the disappearance time (DT50) of glyphosate ranges from 1.7 to 197.3 days, but is typically less than 60 days depending upon edaphic and climatic conditions (Giesy et al., 2000). Due to glyphosate and AMPA's strong adsorptive characteristics, they are not likely to leach to groundwater from the soil; however, monitoring data by USGS demonstrates low amounts of glyphosate and AMPA in groundwater, especially in heavy agricultural areas. In a USGS monitoring study of surface water, groundwater, and soil conducted from 2001 to 2006, the metabolite AMPA was observed more frequently than the parent compound glyphosate (Scribner et al., 2007). Glyphosate and its metabolite AMPA were found in surface water more frequently than groundwater. High levels of glyphosate and AMPA were noted in ground and surface waters were observed when samples were taken from an area with close to agricultural areas that had a recent application of glyphosate coinciding with a recent rain event. Glyphosate was found in rain water; however, this was due to glyphosate's association with particulate matter (dust) and not to its existence as vapor. For an in depth discussion environmental levels of glyphosate in the soil, water, and air, refer to the Technical Report *Effects of Changes in Farming Practices on Water, Soil and Air Due to Use of Glyphosate-Tolerant Alfalfa* (appendix J).

#### 2.2.1.2 Glyphosate Exposure

The Technical Reports *Potential Impacts To Wildlife, Amphibians, Plants And Ecosystems From Increased Glyphosate And Other Chemical Usage* (appendix N), *Health And Safety Risks From Increased Glyphosate And Other Chemical Usage On Humans (Exclusive Of Field Workers)* (appendix L), and *Health And Safety Risks To Field Workers* (appendix M) provide greater detail on glyphosate exposure, refer to these technical reports for further details. A brief overview is provided in this section.

People can be exposed to glyphosate in three ways:

- 1) Inhaling glyphosate (inhalation exposure),
- 2) Absorbing glyphosate through the skin (dermal exposure), and
- 3) Ingesting glyphosate (oral exposure).

These exposures are highly dependant on the use of glyphosate. Glyphosate could enter the body by any one or all of these routes. Glyphosate exposures include agricultural (food); home and personal use (several weed killers contain glyphosate); glyphosate applied to agricultural or residential properties that make their way into the drinking water; or occupational exposure for agricultural workers, field workers, or pesticide applicators. The risk to human and animal health from glyphosate exposure depends on both the toxicity of the glyphosate and the likelihood of people or organism coming into contact with it (exposure).

Listed below are the various exposures scenarios for GT alfalfa:

- Inhalation exposure – agricultural or general public inhaling glyphosate spray
  - Glyphosate does not exist as a vapor under normal conditions; therefore, it is inhaled, small droplets in a aerosolized spray can be inhaled or ingested
- Inhalation exposure – animal inhaling glyphosate spray
  - Glyphosate does not exist as a vapor under normal conditions; therefore, it is inhaled, small droplets in a aerosolized spray can be inhaled or ingested
- Dermal exposure – agricultural or general public absorbing glyphosate during application or during a spill
  - Glyphosate is poorly absorbed through the skin
- Dermal exposure – agricultural or general public absorbing glyphosate from recently treated plants
  - Glyphosate is poorly absorbed through the skin
- Dermal exposure – animals absorbing glyphosate from recently treated plants
  - Glyphosate is poorly absorbed through the skin
- Oral exposure – consuming glyphosate-tolerant alfalfa (humans: tea, sprouts, or herbal supplement; animals: consuming alfalfa)
- Oral exposure – agricultural worker or general public accidental ingestion
- Oral exposure – animal accidental ingestion
- Oral exposure – drinking water containing glyphosate consumed by human
- Oral exposure - drinking water containing glyphosate consumed by animal

The US EPA's toxicological database on glyphosate is considered adequate and complete (US EPA, 2006; 1993), and based on these data, glyphosate is considered to be a toxicologically low-risk herbicide (Cerdeira and Duke, 2006). EPA concluded in (US EPA, 1993, 2006a, 2006b) that glyphosate does not pose a significant risk to human and ecological health, as do the three technical reports listed above that support this EIS. EPA's conclusion that glyphosate does not pose a significant risk to farm workers is confirmed with the *Farm Family Exposure Study* (Acquavella, et al. 2004) a biomonitoring study of pesticide applicators. This biomonitoring study determined that the highest estimated bodily adsorption of glyphosate as the result of routine labeled applications of registered glyphosate-based agricultural herbicides to crops, including glyphosate-tolerant crops, was approximately 400 times lower than the reference dose (RfD) established for glyphosate. Reference dose is the safe level of glyphosate that can be consumed everyday for a lifetime in a human. Furthermore, investigators determined that 40 percent of applicators did not have detectable exposure on the day of application, and 54 percent of the applicators had an estimated bodily adsorption of glyphosate more than 1000 times lower than the RfD (Acquavella, *et al.*, 2004). Use patterns and rates for GT alfalfa are similar to most GT agronomic practices, and in some cases the use pattern for GT alfalfa is less intensive because the perennial nature of alfalfa eliminates the need for annual pre-plant burn down applications which are common in most agricultural crop production. Therefore, the deregulation of glyphosate-tolerant alfalfa would not significantly increase the exposure risk to pesticide applicators.

The biomonitoring study also found little evidence of detectable exposure to individuals on the farm who were not actively involved in or located in the immediate vicinity of labeled applications of glyphosate-based agricultural herbicides to crops. Considering the similarity of the use pattern and application rates of the glyphosate products in this study compared to those registered for use on GT alfalfa and GT crops in general, bystander exposure attributed to the use of glyphosate on glyphosate-tolerant crops is expected to be negligible. However, upper estimates of exposure may be detrimental to infants consuming fruit and all age groups consuming vegetables may be at risk of adverse effects associated with acute exposure to glyphosate. It should be noted, though, that the upper estimates of risk are based on highly conservative fruit and vegetable intake rates; thus it is anticipated that only a very small number of individuals will have this magnitude of exposure and therefore be at this level of risk, further detail can be found in technical report *Health And Safety Risks From Increased Glyphosate And Other Chemical Usage On Humans (Exclusive Of Field Workers)* (appendix L).

#### 2.2.1.3 Glyphosate Surfactant Occurrence and Exposure

Various formulations of glyphosate contain POEA at a level of up to approximately 20 percent (200 g/L). Tallow contains a variety of fatty acids (e.g., oleic, palmitic, stearic, myristic, and linoleic acids), as well as smaller amounts of cholesterol, arachidonic, elaidic, and vaccenic acids.

#### 2.2.1.4 Glyphosate Degradate Occurrence and Exposure

Glyphosate is degraded by soil microbes in the environment to primarily form degradate aminomethyl phosphonic acid (AMPA), which further degrades in the soil to carbon dioxide. AMPA has strong adsorptive characteristics and is not likely to leach to groundwater from the soil; however, monitoring data by USGS demonstrates low amounts of glyphosate and AMPA in groundwater, especially in heavy agricultural areas. A USGS monitoring study of surface water, groundwater, and soil conducted from 2001 to 2006 showed that AMPA was observed more frequently than the parent compound glyphosate (Scribner et al., 2007). AMPA was also found more frequently in surface water than groundwater.

### 2.2.2 Glyphosate Toxicity and Exposure

#### 2.2.2.1 Glyphosate Surfactant Toxicity

While surfactants are typically classified as “inert” components in herbicides, they are not toxicologically inert. In many cases, inerts are found to be more toxic than the herbicide itself (USDA, 2003).

A study evaluating the toxicity of the POEA surfactant included a series of teratology tests in rats using glyphosate (98.7 percent purity), POEA used in glyphosate formulations, and the phosphate ester neutralized POEA. Groups of pregnant female rats were dosed with glyphosate at 300, 1,000, or 3,500 mg/kg/day; POEA at 15, 100, or 300 mg/kg/day, or the neutralized POEA at 15, 50, or 150 mg/kg/day on days 6 through 19 of gestation. Results indicated that severe maternal poisoning occurred at the 3,500 mg/mg/day dose of glyphosate, in association with reduced fetal body weight and sternal ossification, as well as fetal death. At a dose of 300

mg/kg/day of POEA and 150 mg/kg/day of neutralized POEA maternal deaths were also reported. Other noteworthy results in dams were signs of mild clinical toxicity and decreased food consumption that occurred at a dose of 100 mg/kg/day POEA surfactant. No fetotoxic effects were reported at any dose level. Based on these results, the recommended NOAELs for glyphosate, POEA, and neutralized POEA were 1000 mg/kg/day, 15 mg/kg/day, and 50 mg/kg/day, respectively (USDA, 2003).

There has been some debate regarding the acute toxicity of POEA and the determination of its LD<sub>50</sub> value compared to glyphosate. It is generally agreed that the acute toxicity of glyphosate formulations (glyphosate and surfactant; LD<sub>50</sub> in rats 5400 mg/kg/day) is almost equivalent to that of glyphosate (LD<sub>50</sub> in rats 5600 mg/kg/day) (USDA, 2003). Additionally, based on drinking water studies on both glyphosate and Roundup® (i.e., glyphosate with POEA), the surfactant does not affect the rapid elimination rate of glyphosate in mammals (NTP, 1992).

#### 2.2.2.2 Glyphosate Degradate Toxicity

Based on toxicological considerations, a committee of the Health Effects Division (HED) at the EPA's Office of Pesticides Program (OPP) has previously determined that AMPA need not be regulated regardless of levels observed in foods or feeds. Consequently, the terminal residue to be regulated in plants and animals is glyphosate *per se* and AMPA is not included in either the tolerance expression or the risk assessment.

### 2.3 Summary of Findings

The incorporation of the CP4 EPSPS gene into the alfalfa genome allows the ability to identify and quantify its presence or absence in food and feed, especially from the viewpoint of farmers wanting to cultivate non-GE alfalfa.

The lack of detectable presence of intact or immunologically reactive fragments of recombinant plant proteins or DNA in samples of meat, milk, eggs, lymphocytes, blood, and organ tissue obtained from production animals fed GE crops may be partly attributable to the lack of sensitivity of detection methods. More sensitive detection methods could shed more light on this issue. The identified presence of feed-ingested DNA fragments (endogenous and transgenic) in the terminal GI tract in a few cases indicates that uptake into gut epithelial tissue is possible. However, it is suggested that recombinant DNA is likely to be processed in the gut in a manner no different from endogenous feed-ingested genetic material. This shows that the CP4 EPSPS is easily metabolized in the gut of humans and livestock animals. Although CP4 EPSPS can be detected to some degree in processed foods it is not expected to have any toxic effect on humans.

Occupational exposure to glyphosate, AMPA and POEA is expected, especially for farm workers but biomonitoring data shows no cause for concern.

### 3.0 Glyphosate-Tolerant Alfalfa and Unintended Presence

Alfalfa seed growers wish to maintain the genetic integrity of their crops, and in order to maintain variety purity, seed crops are grown under conditions that are designed to keep gene flow restricted to individuals grown in the same field. Two factors that influence the severity and likelihood of breakdowns in seed crop integrity are cross-contamination due to equipment carry-over and gene flow due to cross-pollination.<sup>55</sup> This chapter discusses gene flow due to cross-pollination. The Association of Official Seed Certifying Agencies (AOSCA) and the international Organization for Economic Co-operation and Development (OECD) have developed alfalfa seed production practices that enable growers to meet the Federal Seed Act (7 CFR 201) requirements of greater than 99 percent variety purity for certified seeds and greater than 99.9 percent variety purity for foundation seeds.

With the introduction of glyphosate-tolerant (GT) alfalfa, farmers who want to grow seed or hay crops that have no GT traits<sup>56</sup> questioned whether the AOSCA standards are adequate to meet their needs. Different thresholds for percentage of unintended presence are discussed below:

- Zero (GE-free)<sup>57</sup> – Zero is not statistically provable. All testing methods destroy the sample. Therefore, to be useful, the test can only be run on a portion of the lot.
- No transgene DNA detected by PCR – PCR is the most sensitive test available and a negative result is considered to represent zero, even though true zero is not verifiable on a large sample. PCR is expensive (\$250-\$325 each test) and currently needs to be performed in a laboratory (Mueller, 2005).
- No transgene product (protein) detected by antibody strip test – Tests for transgene protein are not as sensitive as DNA tests, however, they can be field portable and much cheaper (\$5-\$10 each) than PCR tests (Mueller 2005). They are also commercially available and are a standard in the field of testing for GM traits. No detection using an antibody strip test is also often referred to as “zero,” even though statistically it is not. Using a standard strip test protocol to test five 600 seed samples from one seed lot, if all five samples test negative for the transgene protein, then there is a 95 percent confidence that any undetected impurity is less than 0.1 percent (FGI 2007).
- Forage Genetics International (FGI) has a company goal of less than 0.5 percent cross-pollination for all their seed concerning the GT trait. Their current Best Practices achieve 0.180 percent or less unintended presence.
- If more than 0.9 percent transgene protein is detected then the lot must be labeled “genetically modified organism” (GMO) in the European Union.
- If more than one percent transgene protein is detected, then the lot must be labeled GMO in Australia and Brazil.
- If more than three percent transgene protein is detected, then the lot must be labeled GMO in Korea.

---

<sup>55</sup> Intentional presence due to sabotage is also possible, but is not discussed in this report. Inadvertent seed spread due to losses during production and transportation (leaky handling system) are also not addressed in this report (Mallory-Smith and Zapiola, 2008).

<sup>56</sup> “GT trait” refers to both the DNA and the protein it encodes which result in the glyphosate tolerant phenotype. Transgene refers to the DNA, except when followed by “product” or “protein.”

<sup>57</sup> Genetically modified (GM), genetically modified organism (GMO), and genetically engineered or genetically enhanced (GE) are all roughly synonymous terms.

- If more than five percent transgene protein is detected, then the lot must be labeled GMO in Japan.
- In the U.S. National Organic Program (NOP), “certified organic” crops are grown without any intentional inclusion of transgenic seed. Testing for transgene DNA or protein is not required.

Table Q-1 presents nine possible scenarios of gene flow. Each of these scenarios are discussed in this appendix, but are summarized in table Q-1. These nine scenarios are discussed further in section 3.8. The likelihood of viable seed production from each of these scenarios depends on:

- the level of flowering (percent bloom, amount of pollen present),
- the timing of flowering (synchronized flowering),
- bee activity, bee species,
- distance between fields, and
- whether the pollinated flower is cut before seed is produced.

**Table Q-1. Relative Potential for Gene Flow Between Populations of Alfalfa (requires that viable seed is produced) (adapted from Van Deynze et al., 2008)**

| Pollen Donor                   | Pollen Acceptor                                                                                                                                                                                                                                      |                                                                                                                    |                                                                                                                                                                                                  |
|--------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                | Seed field                                                                                                                                                                                                                                           | Hay field                                                                                                          | Feral and other alfalfa                                                                                                                                                                          |
| <b>Seed field</b>              | Without distance between fields, cross pollination between fields would occur at an undesirable rate (if flowering time overlapped). FGI Best Practices that include distance between fields can manage cross-pollination to below 0.5 percent.      | Lowest risk of gene flow because hay is cut before seed is produced.                                               | Feral populations should be controlled near seed fields to preserve seed purity. However, if feral plants are present, they will likely be cross-pollinated by seed field pollen.                |
| <b>Hay field</b>               | The percent bloom at harvest will influence how much pollen could potentially be transported to seed fields. Mowing hay prior to 10 percent bloom and distance (350 to 600 feet) from seed fields can manage cross-pollination to below 0.01 percent | Lowest risk of gene flow out of the nine scenarios. Even in fields that bloom, hay is cut before seed is produced. | The percent bloom at harvest will influence how much pollen could potentially be transported to feral populations. Mowing hay prior to 10 percent bloom can reduce pollen availability.          |
| <b>Feral and other alfalfa</b> | Feral populations need to be controlled near seed fields, or variety purity can be compromised. (Or the seed field edges can be harvested as a separate crop.)                                                                                       | Lowest risk of gene flow because hay is cut before seed is produced.                                               | Gene flow between feral individuals that are close to each other is likely. Gene flow between feral populations depends on proximity, pollinators, flowering timing, and environmental stresses. |

There are different ways to define “populations” of alfalfa. The three population definitions used in this appendix and in table Q-1 are as follows (based partly on Bagavathiannan and Van Acker 2008):

- Hay field population – agricultural field that is intentionally planted with alfalfa and is harvested for hay (may also include some grazing).
- Seed field population – agricultural field that is intentionally planted with alfalfa and is harvested as seed stock.
- Feral and other alfalfa –
- Feral – alfalfa growing on any non-agricultural land (including roadsides, fences, waste lots) that reproduces without intentional human inputs, including reseeding. This is considered the “naturalized” population in the U.S. because alfalfa was introduced to the continent at least 200 years ago (Putnam et al., 2001).
- Habitat/rehabilitation/erosion control – alfalfa that is intentionally sown (most likely in a seed mix), but is not managed after planting.
- Rangeland – seed may be sporadically sown for grazing, but land is not mowed for regular hay harvest, populations are mostly self sustaining.
- Volunteer – alfalfa growing out of rotation in an agricultural field with another crop (e.g., corn).
- Escaped volunteer – alfalfa from seed that escaped from an agricultural field (this is the first generation of a feral population). Escaped volunteers may not persist past a generation or two, depending on conditions.

Key information necessary for evaluating the likelihood of gene flow between populations includes:

- Distribution and quantity of pollen from seed, hay, and feral sources
- Geographic distribution of seed and hay fields, and feral populations
- Temporal distribution of flowers within seed and hay fields, and feral populations
- Seed purity standards and how those standards are achieved and monitored
- Bee behavior and data on bee facilitated cross pollination

### 3.1 Alfalfa Reproduction

Alfalfa is a perennial crop that requires cross-pollination for fertilization, which is performed by insect pollinators. The primary insect pollinators are alfalfa leafcutter bees (*Megachile rotundata*), honey bees (*Apis mellifera*), and alkali bees (*Nomia melanderi*). Alfalfa must bloom, be cross-pollinated by insects, set fruit, and then dehisce seed in order to have offspring. Alfalfa requires at least four weeks of appropriate environmental conditions (temperature, sunlight, nutrients, and water) before forming reproductively mature floral buds, and then four to six weeks after that to form mature seeds after pollination (Rogan and Fitzpatrick, 2004). Viable seeds that fall near adult alfalfa have a harder time growing because they must compete for nutrients with the already established adults, and adult alfalfa plants secrete an autotoxic substance into the soil that inhibits root growth in seedlings (Xuan et al., 2005). In fact, reseeding fields to fill gaps from dead plants is not recommended, as the new plants do not compete efficiently enough to survive (Orloff et al., 1997). However, alfalfa does have a hard

seed that can persist in the environment for several years and alfalfa can shatter and spread seed before harvest (Mallory-Smith and Zapiola, 2008).

Gene flow occurs between populations when genetic information from one population is expressed in the offspring of another population. In plants this can occur through outcrossing, or mating between two different individuals. Some plants primarily self-pollinate, which minimizes gene flow because in those cases, under most conditions, genetic information is rarely exchanged between individuals. Other plants, like alfalfa, mostly outcross, and therefore face the possibility of gene flow between populations. It very rarely self pollinates because of self-incompatibility through failed germination of viable pollen or abnormal pollen tube growth (Bauchan et al., 1990), and instead relies on insects for pollination.

### 3.2 Genetic Integrity

As mentioned above, for alfalfa, pollination and thus gene flow is required for seed production. Alfalfa seed farmers would like to keep pollen flowing within a field, but not between fields. This presents problems when the most common alfalfa pollinators, bees, do not respect farmer field boundaries. Therefore, controlling how pollen is distributed within and among alfalfa fields is dependent on knowledge of bee behaviors and ability to design seed production systems that regulate pollen flow within certain areas, and at the same time restrict pollen flow to other unintended areas. It should be noted that pollen flow and gene flow are not synonymous terms even though they are sometimes used interchangeably. For example, pollen may land on a flower and pollinate it, but if the plant is mowed before seed sets, then gene flow has not occurred.

### 3.3 Pollen from Alfalfa Hay

As noted in table Q-1, the degree to which alfalfa hay can be a source of pollen depends on percentage bloom at harvest. Alfalfa grown for hay will be mowed before setting seed, except in exceptional circumstances which are not explored in this report (e.g., extreme weather events such as tornados that might devastate a local community). Therefore hay fields are the least likely pollen-accepting population of alfalfa. There are numerous citations that claim that alfalfa hay is typically mowed before 10 percent bloom (table Q-2). Because alfalfa hay comprises the majority of the geographic footprint of alfalfa, this assumption (harvest at <10 percent bloom) and possible exceptions to this assumption are explored in this appendix. Key information for estimating potential pollen flow from alfalfa hay is how much the field blooms before it is harvested. Monsanto requires that farmers sign a Monsanto Technology/Stewardship Agreement (MTA) which stipulates that farmers must harvest GT alfalfa hay prior to 10 percent bloom (Monsanto, no year). Presumably farmers that prefer to harvest later would not adopt GT alfalfa or would change their harvesting time. No information on farmer compliance with the MTA was found. The discussion in this section investigates the premise that alfalfa hay is only rarely harvested later than 10 percent bloom. The discussion does not apply to GT alfalfa if farmers comply with the MTA.

### 3.3.1 *Recommended Harvest Timing*

Some of the factors that influence farmers' timing of hay field harvests include:

- Predicted quality – Younger plants have higher forage digestibility and protein content, therefore hay from young plants receives the highest grades (and highest price per ton).
- Predicted yield – Yield is based on the biomass of the harvested portion of the plant. Alfalfa reaches its greatest biomass and therefore greatest yield potential at full bloom. During seed set yield decreases. A full bloom field may produce the highest tonnage, but the hay receives a lower grade based on digestibility and protein content.
- End hay user needs (self or buyer) – The highest grade hay is best for dairy cattle because it maximizes milk production and merits its higher price. Heifers (immature dairy cattle), beef cattle, horses, and other livestock do not benefit from the highest grade hay in a way that provides economic gain to farmers; therefore lower grades are acceptable and even desirable for these animals.
- Stand health – Mowing patterns can influence stand health and longevity.
- Root reserves – Stand life can be reduced if alfalfa is repeatedly cut before root reserves are restored. In regions that experience harsh winters adequate root reserves are essential for plant survival. Root reserves are at their lowest during the bud stage and are at their highest from full bloom to seed set (Shroyer et al., 1984; Hesterman and Durling, 1991; Howley and Wright, 1991).
- Weed control – In fields with severe weed problems, early mowing can rescue a stand (Orloff et al., 1997).
- Pest control – Mowing can reduce insect pests (Lee et al., no year).
- Weather – Wet weather can delay mowing and impact drying (for baled hay).

The factors presented above are illustrated by examples in table Q-2. Most of the sources of information in table Q-2 are state university Agricultural Extension publications. There is general agreement that the best balance between high quality and yield is to harvest at or before 10 percent bloom (table Q-2; Undersander and Pinkerton, 1989).

**Table Q-2. Alfalfa Dry Hay Harvest Statistics and Recommendations**

| State        | Growing Region              | Percent of Harvest Acres (2005) | Percent of Organic Harvest Acres (2005) | Harvest Advice                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            | Source                |
|--------------|-----------------------------|---------------------------------|-----------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------|
| South Dakota | North Central               | 10.70                           | 6.82                                    | Alfalfa for hay is harvested in generally one to four cuttings per year, depending on location within the state. Western areas of the state often receive only one cutting per year due to low rainfall, whereas southeast South Dakota usually can support four and occasionally five cuttings per year. Highest quality hay is taken when alfalfa plants are in pre-bud to early bud.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   | Wilson, no year       |
| Montana      | Winter Hardy Inter-mountain | 7.80                            | 2.60                                    | Alfalfa plants are injured or weakened if cut when the root reserves are low—usually three weeks after growth begins or after cutting. Harvest timing is most critical in the fall. Alfalfa plants must be able to make sufficient fall growth to store large quantities of carbohydrates in the roots. These reserves help to prevent winterkill and provide rapid spring growth. To assure adequate food reserves in the roots, the alfalfa plants should have at least 30 days of regrowth before being killed by frost. Determine when the first killing frost for your area occurs, and make your last cutting 30 days before that date. Alfalfa regrowth should not be harvested or pastured in the fall until several killing frosts cause the plants to become dormant. Average dates of killing frosts for most areas of Montana are available and should be considered when scheduling the last hay harvest. Harvesting at the early-bloom stage will reduce leaf and stem shatter and cut the losses. Harvesting the forage as silage can save considerable feed value. Weather forecasts should be watched closely, since it is better to delay cutting than to suffer excessive rain damage. | Baldrige et al., 1985 |

|--------------|----------------|---------------------------------|-----------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------|
| North Dakota | North Central  | 7.35                            | 10.09                                   | <p>NEW PLANTINGS--Alfalfa harvested during the establishment year should grow to the 10 to 25 percent bloom growth stage before harvesting the first cutting to enable the young plants to become well established, although earlier harvest has not been detrimental to stands in high-moisture areas. Alfalfa seeded with a companion crop usually does not grow tall enough after removing the companion crop for an economical forage harvest. If sufficient growth is obtained, it usually occurs in September, and harvest should be delayed until air temperatures have dropped low enough to restrict regrowth, or until just prior to or immediately after the first killing frost.</p> <p>ESTABLISHED STANDS--should be harvested using a combination of growth stage and calendar date to determine the best harvest date. The first cutting must usually be taken before mid-June to allow time for three cuttings prior to August 20-25 in an average year. The first crop should be harvested by the 10 percent bloom stage (late bud to early bloom), especially in the Red River Valley area or under irrigation where three annual cuttings usually are obtained. Delayed harvest lowers the quality of the first harvest the most. Advantages of an early harvest are that a near maximum yield of quality forage is obtained, root reserves for regrowth have been adequately replenished, and soil water usually remains to initiate new growth. Forage quality of second and third-cut alfalfa is less affected by delayed harvest. Harvesting third cutting at 10 to 50 percent bloom will allow buildup of root reserves to aid in overwintering, and forage will be of high quality.</p> | Meyer and Helm, 1994 |
| Wisconsin    | North Central  | 6.91                            | 14.38                                   | <p>There is no simple alfalfa cutting schedule recipe or rule of thumb that will apply every year or for every farm. However, for an alfalfa enterprise to be profitable, producers must optimize forage yield, quality, and stand persistence. Estimating first cut forage quality before the crop is actually harvested is now possible with the availability of scissor cut results on an area basis and making PEAQ estimates on an on-farm basis. Use these tools to make first cut harvest decisions. Summer cuts will typically be made at 35 to 40 day intervals unless environmental factors deviate significantly from normal. Plan to be out of alfalfa fields by about August 25th and make late fall cutting decisions based upon forage need under the realization that stand persistence and subsequent plant vigor will be put at risk</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | Rankin, no year      |

| Minnesota  | North Central                                   | 6.02                            | 10.44                                   | In stands which are in the first season of production (the seeding year), one fourth of growers take no cuttings, one quarter take one, one quarter take two, and one quarter take three cuttings. In established stands, a majority of Minnesota growers (about 70 percent) take three cuttings per year. About one-fourth take two cuttings per year, and a fourth cutting is taken by about 10 percent of growers. Most growers harvest alfalfa when the stand is at 10 percent bloom; if four cuttings are made, a greater percentage of growers harvest when the stand is at pre-bloom. Mid-August through mid-September is when almost all Minnesota growers take the last cutting of the season.                                                                                                                                                                                         | Nelson, 2000                                 |
| Iowa       | North Central                                   | 5.57                            | 4.50                                    | For maximum yields, it is important to have 20-30 plants per square foot during the seedling year for protection against weed competition. Do not harvest alfalfa seeded in late summer until the following spring. Allow new seedlings to start to bloom before the first harvest. Cut alfalfa three-four times a year when stand is 25 percent flowered.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      | Welter Seed, no year                         |
| California | Moderate Winter Hardy Inter-mountain/ Southwest | 4.63                            | 6.48                                    | In the Intermountain Region, it takes 3 to 4 weeks to restore root reserves and another 7 to 10 days to add surplus carbohydrates to the roots so the plant is ready for another cutting. Hay intended for this [dairy] market must be cut early (late-bud stage at the latest) for the necessary quality to be achieved. Conversely, hay intended for beef cattle or horses can be cut later, at 10- to 30-percent bloom, to maximize yields with acceptable quality for these classes of livestock.                                                                                                                                                                                                                                                                                                                                                                                           | Orloff and Putnam, 2007; Orloff et al., 1997 |
| Michigan   | East Central                                    | 4.01                            | 0.35                                    | (1) Schedule your cuttings based upon alfalfa stage of growth and your goals for forage production. Harvest at the early bloom stage of growth to maximize nutrient yield per acre and ensure that root reserves have been restored to a reasonably high level. Harvesting earlier maximizes forage quality but does not ensure adequate levels of stored root reserves. Harvesting later maximizes yield and stored root reserve levels but forage quality is lowered. (2) Offset the risk of winter injury by selecting multiple disease resistant, winter hardy varieties, maintaining young stands, keeping soil fertility levels high, growing alfalfa on well drained soils, and retaining snow in the winter if possible. (3) Delay the first cutting of winter-injured stands until full bloom. If alfalfa plants were frost heaved, cut above the normal height to avoid crown injury. | Hesterman and Durling, 1991                  |

|----------|-----------------------------|---------------------------------|-----------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------|
| Kansas   | Great Plains                | 3.79                            | 0.32                                    | On established stands the first cutting should be made when regrowth at the crown is observed; subsequent cuttings can be made at one-tenth bloom or 28-30 day intervals if weather conditions allow. Severe leaf loss may initiate cutting to salvage the hay crop and maintain stands. If this occurs the next cutting should be delayed to allow the root reserves to be replenished. Cutting at the pre-bud and bud stage produces a higher quality forage than at later stages, but repeatedly cutting at early stages reduces root reserves which results in poor stands and lower yields. Cutting when regrowth at the crown appears and at one-tenth bloom maximizes forage yield, quality and benefits stand longevity. The last cutting before fall dormancy should allow four to five weeks of growth so that root reserves are replenished. | Shroyer et al., 1984  |
| Colorado | Winter Hardy Inter-mountain | 3.57                            | 4.38                                    | If highest quality is the primary consideration, harvest at the bud stage during each regrowth cycle. Many growers, however, produce alfalfa hay that is sold or fed on the basis of less than premium quality standards. For these producers, the optimum growth stages for harvest are mid- to late bloom, because higher yields can be obtained and quality is still acceptable.<br>Alfalfa grown in Colorado below 7,000 feet can be harvested in late summer or early fall with little concern for timing relative to the first killing frost (28 degrees F). Regardless of the amount of regrowth at the time of frost, fall conditions almost always are mild enough to allow for adequate recharge of reserves. Above 7,000 feet, it generally is best not to cut within four weeks of the average date of the first killing frost.             | Smith et al., 1998    |
| Wyoming  | Winter Hardy Inter-mountain | 2.67                            | 0.84                                    | Alfalfa should be harvested at the late bud to early bloom (10 percent bloom) stage for premium hay. Delaying harvest will reduce the hay quality. Taking the first cutting early will control weevil problems. In fall-planted alfalfa, first harvest occurs in late May to June, depending on the region and time of planting. Subsequent harvests are approximately every 28 days, as long as the late bud to early bloom stage of development has been reached (second harvest usually in July, third harvest September 1 - 15). The last harvest of the season should be at least two weeks before the first killing frost. At high elevations, 8 - 14 drying days are needed between cutting and baling the hay.                                                                                                                                  | McDonald et al., 2004 |

| Ohio         | East Central   | 2.27                            | 0.50                                    | When harvests are made at late bud-early bloom stage of development, the fall cutting schedule is important for stand maintenance. Make the last regular harvest by the calendar: northern Ohio, September 1 to 7; central Ohio, September 3 to 12; southern Ohio September 5-15. This means that on those fields with an intensive cutting schedule, no harvest should be taken from early-mid September to mid-October. At least 30 days between the last regular harvest and killing frost are needed to adequately restore root and crown reserves.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            | Myers and Van Keuren, no year |
| Pennsylvania | East Central   | 2.27                            | 0.60                                    | During the year of establishment, seedlings need a high level of energy reserves in order to persist through the winter. For spring seedings made without a companion crop, two harvests can generally be made the first year, provided the crop has adequate rainfall and optimum levels of soil nutrients. The first harvest can be made before flowers begin to appear, but waiting for the alfalfa to flower will ensure greater energy reserves in the roots. Alfalfa will generally reach this stage of development between 60 and 70 days after emergence. The second harvest should either be made before September 1, to ensure an adequate buildup of energy reserves for winter, or be delayed until after the first killing frost (24°F) in the fall or after mid-October. Occasionally, when the second harvest is made before September and there are good fall growing conditions, a third harvest may be made after a definite killing frost. When mid-October or later harvests are made, a high stubble (6 inches) should be left for ground cover to protect the crowns and to catch snow for added insulation. | Bosworth et al., no year      |
| Missouri     | East Central   | 2.01                            | 0.58                                    | For spring-seeded established stands in the seeding year, take the first harvest at the mid- to full-bloom stage. Make following harvests as flowers begin to appear. For established stands, take the first (May 10 to 20) and second (June 15 to 25) cuttings when the plants are just beginning to bloom. For persistence of the stand, make two more harvests at about 35-day intervals before Sept. 15. Harvesting alfalfa in the bud stage produces five cuttings of high-quality hay before Sept. 15. This practice, however, reduces stand life to three or four years.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    | Henning and Nelson, 1993      |

| New York   | East Central       | 2.01                            | 0.16                                    | As a general guideline, all perennial forages should be harvested at early stages of maturity when both palatability and nutrient content are high. For alfalfa, the neutral detergent fiber (NDF) value should be approximately 40 percent. This occurs at a late bud stage for the spring harvest of alfalfa. Early harvest also allows time for regrowth and subsequent harvests during the growing season. Alfalfa can be harvested two to four times a year in New York, depending on the growing season and soil type. Alfalfa stands will persist longer if there is a forty- to forty-five-day interval between harvests. All studies comparing various harvest schedules indicate that four harvests per year decrease the long-term persistence of stands compared to three harvests per year. Frequent harvests, with a shorter interval between, may be more advantageous in short rotations, where stands of alfalfa are only kept down for two to three years. | Cherney et al., 2001      |
| Washington | PNW-Inter-mountain | 2.01                            | 0.56                                    | High-quality dairy hay, which brings the highest price, is harvested during the late bud stage of growth before any sign of bloom. Growers can discern bud stage by simply walking through the field and feeling the terminals of the tallest stems. Buds about to open have a hard lump inside the terminal growth point. Dairy-quality hay is harvested on an average of every 30 days, starting in late May or early June and continuing through September. Alfalfa hay for the horse market requires lower protein and higher fiber. More mature hay with up to 50 percent bloom can be desirable for this market. This growth stage is attained by delaying harvest to 35- to 37-day intervals. In the southern growing areas, 4 to 5 harvests are taken, while in the northern areas 3 to 4 harvests are taken each year.                                                                                                                                              | Kugler and Woodward, 2006 |
| Oklahoma   | Great Plains       | 1.43                            | 0.04                                    | The best time to harvest will vary, depending on projected use of hay. If hay will be sold as high-quality forage (for dairy cattle), alfalfa should be cut at bud stage or earlier (28 day cycle or less). If alfalfa is being used as feed for a cow-calf operation where high quality is not as critical, it should be cut at 25-50 percent bloom stage (35-42 day cycle) to maximize yield.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              | Caddel et al., 2001       |

| Virginia   | East Central                                    | 0.49                            | 0.14                                    | Harvesting usually occurs at late bud to 1/4 bloom, except the first cutting. The first cutting should be made in (hay or silage) bud stage or when orchard grass begins to head. Alfalfa may be cut 3-5 times/year at 30- to 40-day intervals, depending upon location in the state and average rainfall. Make the last cutting three to four weeks before average date of first killing frost in fall or in time to allow 6-8 inches of regrowth. Allow at least one harvest to reach 1/10 bloom to help persistence. | Schooley et al., 2004   |
| Tennessee  | East Central                                    | 0.16                            | 0.00                                    | New spring seedlings should be harvested when they reach full bloom. All other harvests should be made when 10 percent of the plants are blooming. Fall seeded and established stand may be harvested at the bud stage for the first cutting, and then at the 10 per cent bloom stage for all later cuttings. Last harvest should be made before mid-September.                                                                                                                                                         | Bates, 1998             |
| New Jersey | East Central                                    | 0.11                            | 0.00                                    | Usually, when following cutting intervals closely, the alfalfa will be in the pre-bud to bud stage, which is ideal for harvesting, providing the highest nutrient levels and greatest digestible content for livestock. Farmers are encouraged to harvest the crop early rather than use pesticides if pest populations are over thresholds.                                                                                                                                                                            | Lee et al., no year     |

| State         | Growing Region | Percent of Harvest Acres (2005) | Percent of Organic Harvest Acres (2005) | Harvest Advice                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                | Source        |
|---------------|----------------|---------------------------------|-----------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------|
| Massachusetts | East Central   | 0.06                            | 0.00                                    | Careful management of new seedlings is especially important in the seeding year to ensure a long-lived productive stand. New seedlings should not be harvested until plants have come to at least the one-half bloom stage to ensure adequate storage of total nonstructural carbohydrates (TNC) in the roots. This management should be followed for all harvests in the seeding year. Established stands of alfalfa can survive earlier harvesting in the spring than that recommended for new seedlings. Removal of first cuttings at the full bud stage in the spring does not reduce the annual forage yields appreciably. It may even be necessary to spread the harvest period of each cut or may be desirable to improve forage quality and to prevent over-mature hay crops. Because the effects of early cutting are accumulative, the practice of cutting at early growth stages should be rotated among alfalfa fields. Alfalfa stand will not be reduced from a single cut at the bud stage, provided successive cuttings are permitted to reach at least the one-tenth bloom stage of maturity. | Herbert, 1996 |

### 3.3.2 *Quality of Hay is Dependent on Timing of Harvest*

Quality of hay can be measured by several different variables. Although quality can be partially predicted by time of harvest based on percentage of bloom, many buyers require nutrient testing (Robinson et al., 2007). USDA has both narrative and numeric criteria for grading hay. USDA Agricultural Marketing Service (AMS) Market News uses the following visual physical descriptions for quality (<http://www.ams.usda.gov/mnreports/lamllgr311.pdf>):

- Supreme: Very early maturity, pre bloom, soft fine stemmed, extra leafy. Factors indicative of very high nutritive content. Hay is excellent color and free of damage.
- Premium: Early maturity, i.e., pre-bloom in legumes and pre head in grass hays, extra leafy and fine stemmed-factors indicative of a high nutritive content. Hay is green and free of damage.
- Good: Early to average maturity, i.e., early to mid-bloom in legumes and early head in grass hays, leafy, fine to medium stemmed, free of damage other than slight discoloration.
- Fair: Late maturity, i.e., mid to late-bloom in legumes, head-in grass hays, moderate or below leaf content, and generally coarse stemmed. Hay may show light damage.
- Utility: Hay in very late maturity, such as mature seed pods in legumes or mature head in grass hays, coarse stemmed. This category could include hay discounted due to excessive damage and heavy weed content or mold. Defects will be identified in market reports when using this category.

The stages of maturity mentioned in the list above are defined as follows (Bagg, 2003):

Late vegetative – No visible buds, stem at least 12 inches tall.

Early bud – Visible flower buds on at least 1 stem.

Mid bud – 50 percent of stems have at least 1 bud.

Late bud – 75 percent of stems have at least 1 bud, no visible flowers

First bloom – Flowers on at least 1 stem.

1/10 bloom (Early bloom) – 10 percent of stems have at least 1 flower.

Mid bloom – 50 percent of stems have at least 1 flower.

Full bloom – 75 percent of stems have at least 1 flower.

Hay is tested by certified laboratories for acid detergent fiber (ADF), neutral detergent fiber (NDF), crude protein (CP), and dry matter (DM). Total digestible nutrients (TDN) is calculated from ADF. Table Q-3 presents the numeric criteria for these hay quality components. Note that only 10 percent grass (either from livestock edible weeds or companion crops) is allowed.

**Table Q-3. USDA AMS Alfalfa Guidelines (for domestic livestock use and not more than 10 percent grass)**

| Quality | ADF   | NDF   | *RFV    | **TDN-100 percent | **TDN-90 percent | CP    |
|---------|-------|-------|---------|-------------------|------------------|-------|
| Supreme | <27   | <34   | >185    | >62               | >55.9            | >22   |
| Premium | 27-29 | 34-36 | 170-185 | 60.5-62           | 54.5-55.9        | 20-22 |
| Good    | 29-32 | 36-40 | 150-170 | 58-60             | 52.5-54.5        | 18-20 |
| Fair    | 32-35 | 40-44 | 130-150 | 56-58             | 50.5-52.5        | 16-18 |
| Utility | >35   | >44   | <150    | <56               | <50.5            | <16   |

\*RFV calculated using the Wis/Minn formula. \*\*TDN calculated using the western formula. Quantitative factors are approximate, and many factors can affect feeding value. Values based on 100 percent dry matter (TDN showing both 100 percent & 90 percent). Guidelines are to be used with visual appearance and intent of sale (usage).

USDA's Natural Resources Conservation Service (NRCS) provides the following key to nutrient values and maturity levels for legumes, grass, and grass/legume mixtures (table Q-4).

**Table Q-4. Quality standards for legume, grass, and grass and legume mixture (USDA NRCS 2002)**

| Maturity      | ADF   | NDF   | RFV     |
|---------------|-------|-------|---------|
| Pre-bloom     | <31   | <40   | >151    |
| Early bloom   | 31-35 | 40-46 | 151-125 |
| Mid bloom     | 36-35 | 47-53 | 124-103 |
| Full bloom    | 41-42 | 54-60 | 102-87  |
| Rain damaged  | 43-45 | 61-65 | 86-75   |
| Severe damage | >45   | >65   | <75     |

The AMS maturity-to-protein-content categories do not seem to agree with the NRCS table Q-4. For example, the Fair category is described as mid to late bloom in the AMS narrative standards and has an ADF of 32-35, NDF of 40-44, and RFV of 130-150. In the NRCS table similar nutrient levels are categorized as early bloom. The one difference between the two sources is that AMS alfalfa guidelines are for legumes with less than 10 percent grass and the NRCS table is for legume, grass, and grass and legume mixtures of unspecified percentages. Because grass has lower nutrient value than legumes, legume/grass mixtures would have to be harvested earlier to achieve the same nutrient ratings as pure legumes. Therefore, for alfalfa stands with less than 10 percent grass, the AMS table may be more accurate.

Iowa State University Extension has created a tool for alfalfa farmers in Iowa that can help them predict the RFV of the first harvest of the year (Lang, 2001). The Predictive Equations for Alfalfa Quality (PEAQ) allows growers to use height of tallest stem (in inches) and the maturity of the most mature stems to predict RFV, then subtract 10 to 20 RFV units for losses during harvest. This tool is helpful because climatic differences from year to year make calendar date harvesting unreliable. The tool has been validated in the Midwest and other environments in California and New York. Lang (2001) recommends 150 RFV for milking dairy herds, and 120 to 130 for heifers, stocker cattle and lactating beef cattle. So for hay to achieve RFV of 150, late vegetative (no visible buds) corresponds with 28 inches in height, bud stage (no flowers) corresponds with 26 inches in height, and flower stage (1 or more nodes with open flowers) corresponds with 24 inches in height. So clearly maturity based on bloom is not fully predictive of nutrient content.

If the AMS narrative criteria could be taken at face value, then a crude estimate of the tonnage of hay alfalfa that goes to mid and late bloom could be estimated by examining the quantity of hay

sold in the good and fair categories. USDA Market News tracks alfalfa hay prices on a weekly basis for some regions. The alfalfa hay market for June, 2008 is summarized in table Q-5. Only data for California, Nevada, Idaho, Washington, and Oregon included information on tonnage. For other states and regions average prices were reported, but not tonnage. Factors that contribute to the inaccuracy of this crude estimate include:

Nursery crops – Annual companion crops that are interseeded with alfalfa to reduce weed growth during stand establishment (first year) typically have lower protein content than alfalfa.

Therefore the presence of companion crop in a harvest can lower the quality of the hay regardless of the maturity of the alfalfa. This factor applies mainly to the first year of stand life because established alfalfa is a good competitor and companion plants are reduced.

Weeds – The prevalence and protein content of weeds in any given batch of alfalfa is unknown and highly variable. In general weeds lower alfalfa protein quality and overall quality regardless of alfalfa maturity level at harvest.

Tonnage ≠ Acreage – Yield (tons/acre) is not consistent between the quality categories. Because the biomass of the alfalfa is lower when the plants are younger, harvesting supreme and premium hay results in lower yields. If the alfalfa is permitted to gain more biomass yield is higher, but the quality of the hay drops to good or fair. Therefore tonnage does not indicate acres. In addition yield also fluctuates due to many other factors, both environmental and farm management.

Based on June, 2008 data for the five Western states listed in table Q-4, 57 percent of the alfalfa hay sold was in the supreme and premium categories, which are harvested before flowers mature. Forty three percent of the tonnage was in the good to fair categories. Based on the category descriptions one might conclude that 43 percent of the tonnage was harvested at 10 to 75 percent bloom. Again it should be noted that tonnage does not translate to acreage because yield (tons/acre) increases the later in maturity that alfalfa is cut. Since 15 percent of the harvest was sold as fair, it could be that 15 percent of the tonnage (not acreage) was harvested no sooner than 50 percent bloom. Clearly this crude calculation is not adequate to truly estimate pollen availability. In addition, the geographic breakdown is not fine enough to be helpful, because the markets in table Q-5 are hundreds of square miles in size and pollen flow happens at the scale of feet to a few miles. However, based on this crude calculation, it may be inaccurate to make the blanket statement that alfalfa hay is harvested at less 10 percent bloom except in rare cases. However, this statement may be accurate for GT alfalfa because farmers that purchase GT alfalfa seed are required to agree to harvest at less than 10 percent bloom. Presumably farmers that prefer to harvest at later bloom stages would not adopt GT alfalfa.

**Table Q-5. Alfalfa Hay Market – Tons and Quality Rating (Month of June 2008)<sup>58</sup>**

### 3.4 Flowering Time

Flowering of seed fields and hay fields may not be synchronized, depending on mowing schedules, inputs (irrigation, fertilizer), and cultivar. For cross pollination to occur, the flowers must be blooming at the same time. Within a field this is fairly simple to synchronize because the seeds are planted at the same time and varieties are bred to have low variability in germination time within varieties.

Alfalfa flowers for an amount of time that is dependent on factors such as region where it is grown, management practices and the species of pollinators used. In general, alfalfa will bloom longer and open flowers will accumulate when fewer pollinators are present, but there will be a decrease in standing crop of open flowers in the presence of many pollinators. After the alfalfa has been pollinated, it no longer devotes energy to flower production, but instead diverts energy to fruit development. This is evidenced by the fact that after pollination, nectar production ceases and wilting occurs in about 4 hours at warm temperatures, or 24 hours at cool temperatures (Strickler and Vinson, 2000). Different pollination management strategies will affect the blooming duration for alfalfa. For example, in regions where alfalfa leafcutter bees are used, they are released quickly after bloom and large numbers are released at once (up to 52,000 females per hectare). This would result in a short duration of open alfalfa flowers. In regions where honey bees are used for pollination, such as California, fewer bees are used and pollination occurs at a more moderate pace, leading to a longer bloom time for alfalfa (Strickler and Freitas, 1999)

In a study in Idaho (Strickler and Freitas, 1999), alfalfa leafcutter bees were released when the alfalfa had started blooming, and because the bees need a couple of weeks to establish their nests, stabilize themselves, and reach constant rates of foraging (Bosch and Kemp, 2005), the amount of flowers reached a peak two weeks after bee release. After this point and once the pollinators began steadily foraging, the amount of flowers decreased exponentially and moved to seed production. Twenty-five percent of the peak bloom was present four weeks after pollinator release. This pattern was also observed in fields in Oregon (Bosch and Kemp, 2005), where flowers accumulated for the first three weeks of the study, and by week four, one to two weeks after alfalfa leafcutter bee release, the standing crop of flowers decreased rapidly.

Hay fields are treated differently than seed fields, and are typically cut when the field is at one-tenth bloom. About four weeks are allowed to pass between cuttings, to allow fields to reach one-tenth bloom again. Figure Q-3 shows one possible typical pattern of alfalfa blooming for seed fields, including pollinator introduction (alfalfa leafcutter bees) and seed formation, with hay field bloom and cutting overlaid. If these two fields were geographically close enough that pollinators could visit both fields, the potential for pollen exchange would only occur when the curves overlap. In figure Q-3 the hay and seed field start synchronized. The figure illustrates the relatively short amount of time that hay and seed field bloom would overlap. Note the hay field is harvested at 10 percent bloom.

**Figure Q-3: Flowering overlap between hay and seed fields**

### 3.5 Forage and Seed Field Proximity

The Agricultural Resources and Environmental Indicators Database has a mapping tool that converts agricultural data to map form (<http://maps.ers.usda.gov/AgResources/index.asp?Describ=Alfalfa+hay+%28tons%2C+dry%29%2C+harvested+%28acres%29&TableNo=28&CatalogVal=Field+Seeds%2C+Grass+Seeds%2C+Hay%2C+Forage%2C+and+Silage&Year=D97&Type=Total&drawtype=drawmap&action=&boundaryflag=&labelflag=&drawtypesaved=drawmap&sort=&sorttype=&printflag=&yearvalue=D97&x=280&y=187>). It contains data on alfalfa hay and seed production for the United States from 1997, and shows the approximate distribution of this production. As the color gets darker, production increases. This gives a visual idea of the regions of the country with the most alfalfa, and shows that seed production is far less than hay

production and is more geographically clustered. Figure Q-4 presents alfalfa hay acreage and figure Q-5 presents alfalfa seed acreage.

presents alfalfa

**Figure Q-4: 1997 Alfalfa hay (tons, dry), harvested (acres)**

**Figure Q-5: 1997 Alfalfa seed (pounds), harvested (acres)**

Forage and seed field data for 2007 is presented in table Q-6. Alfalfa hay and seed production occurs mainly in the west and northwest United States. The biggest producers of hay (pounds) are California, South Dakota, and Idaho, while the biggest producers of seed (pounds) are California, Washington, and Idaho. When looking at acreage, however, South Dakota, Montana and Wisconsin have the largest hay production, while California, Washington and Idaho have the most acreage for seed production. Acreage might be a more important concern when looking at gene flow, as the spatial distribution of alfalfa fields is a factor in determining the potential of pollination. California, Washington and Idaho would be the states that would most likely have farmers concerned about the adventitious presence of the GT trait, as they not only have the most acreage devoted to seed production, but also produce the most seed in the country.

Roundup® is only registered for alfalfa seed production in 13 states: Arizona, California, Colorado, Idaho, Montana, Nevada, New Mexico, Oklahoma, Oregon, Texas, Utah, Washington, and Wyoming. There are several states which produce seed but would not be able to produce GT alfalfa seed because Roundup® is not approved for use on seeds: South Dakota, North Dakota, Minnesota, Kansas, and Nebraska (FGI, 2007).

**Table Q-6. Top 20 States for Alfalfa Hay and Seed Acreage and Quantity, 2007 U.S. Census of Agriculture**

### 3.6 Seed Purity Standards and Requirements

Alfalfa farmers follow state mandated certification standards when cultivating seed crops. These standards vary based on the state and the level of certification desired, and outline guidelines for the management of seed crops. The Association of Official Seed Certifying Agencies (AOSCA) is an overview body that assists these state-level offices in producing, identifying, distributing and promoting various classes of seed. The AOSCA provides the alfalfa seed certification standards for each state to the public ([www.aosca.org](http://www.aosca.org)). These are based on the Federal Seed Act (7 CFR part 201) which is as follows (only standards for alfalfa and applicable footnotes are shown)( <http://ecfr.gpoaccess.gov/cgi/t/text/text-idx?c=ecfr&sid=b2641469d5186de8667eaef9eb58e654&rgn=div8&view=text&node=7:3.1.1.7.27.0.327.109&idno=7>):

#### Title 7: Agriculture

#### PART 201—FEDERAL SEED ACT REGULATIONS

##### Certified Seed 4.2.1.1.1

##### § 201.76 Minimum Land, Isolation, Field, and Seed Standards.

In the following table Q-7 the figures in the “Land” column indicate the number of years that must elapse between the destruction of a stand of a kind and establishment of a stand of a specified class of a variety of the same kind. A certification agency may grant a variance in the land cropping history in specific circumstances where cultural practices have been proven adequate to maintain genetic purity. The figures in “Isolation” column indicate the distance in feet from any contaminating source. The figures in the “Field” column indicate the minimum number of plants or heads in which one plant or head of another variety is permitted. The figure in the “Seed” column indicates the maximum percentage of seed of other varieties or off-types permitted in the cleaned seed.

**Table Q-7. Minimum Land, Isolation, Field and Seed Standards (7 CFR 201.76)**

| Crop           | Foundation     |                                                  |                     |      | Registered     |                                                   |       |      | Certified        |                                                   |                   |      |
|----------------|----------------|--------------------------------------------------|---------------------|------|----------------|---------------------------------------------------|-------|------|------------------|---------------------------------------------------|-------------------|------|
|                | Land           | Isolation                                        | Field               | Seed | Land           | Isolation                                         | Field | Seed | Land             | Isolation                                         | Field             | Seed |
| <b>Alfalfa</b> |                |                                                  |                     |      |                |                                                   |       |      |                  |                                                   |                   |      |
| Non hybrid     | 4 <sup>1</sup> | 600 <sup>44,48</sup><br>(182.88m <sup>59</sup> ) | 1,000               | 0.1  | 3 <sup>1</sup> | 300 <sup>3,44,48</sup><br>(91.44m <sup>59</sup> ) | 400   | 0.25 | 1 <sup>1,2</sup> | 165 <sup>44,49</sup><br>(50.29m <sup>59</sup> )   | 100               | 1.0  |
| Hybrid         | 4 <sup>1</sup> | 1,320 <sup>43</sup><br>(402.34m <sup>59</sup> )  | 1,000 <sup>42</sup> | 0.1  |                |                                                   |       |      | 1 <sup>1,2</sup> | 165 <sup>3,43,44</sup><br>(50.29m <sup>59</sup> ) | 100 <sup>42</sup> | 1.0  |

<sup>1</sup>The land must be free of volunteer plants of the crop kind during the year immediately prior to establishment and no manure or other contaminating material shall be applied the year previous to seeding or during the establishment and productive life of the stand.

<sup>2</sup>At least 2 years must elapse between destruction of indistinguishable varieties or varieties of dissimilar adaptation and establishment of the stand for the production of the Certified class of seed.

<sup>3</sup>Isolation distance for certified seed production shall be at least 500 feet (152.07m) from varieties of dissimilar adaptation.

<sup>42</sup>The ratio of male sterile (A) strains and pollen (B or C) strains shall not exceed 2:1.

<sup>43</sup>Parent lines (A and B) in a crossing block, or seed and pollen lines in a hybrid seed production field, shall be separated by at least 6 feet (1.83m) and shall be managed and harvested in a manner to prevent mixing.

<sup>44</sup>Distance between fields of certified classes of the same variety may be reduced to 10 feet (3.05m) regardless of the class or size of the fields.

<sup>48</sup>This distance applies for fields over 5 acres (2ha). For alfalfa fields of 5 acres (2ha) or less that produce the Foundation and Registered seed classes, the minimum distance from a different variety or a field of the same variety that does not meet the varietal purity requirements for certification shall be 900 feet (274.32m) and 450 feet (137.16m), respectively.

<sup>49</sup>There must be at least 10 feet (3.05m) or a distance adequate to prevent mechanical mixture between a field of another variety (or non-certified area within the same field) and the area being certified. The 165 feet (50.29m) isolation requirement is waived if the area of the “isolation zone” is less than 10 percent of the field eligible for the Certified class. The “isolation zone” is that area

calculated by multiplying the lenGRh of the common border(s) with other varieties of alfalfa by the average width of the field (being certified) falling within the 165 feet (50.29m) isolation. Areas within the isolation zone nearest the contamination source shall not be certified.

<sup>59</sup>Indicates metric equivalent in meters.

[59 FR 64516, Dec. 14, 1994, as amended at 65 FR 1710, Jan. 11, 2000]

California, the largest producer of seed alfalfa, outlines typical guidelines for field eligibility (past use and spatial isolation) and seed purity standards ([http://ccia.ucdavis.edu/seed\\_cert/alfalfa\\_seedcert\\_standards.htm](http://ccia.ucdavis.edu/seed_cert/alfalfa_seedcert_standards.htm)). For cultivating Foundation seed, seed of the highest purity, alfalfa must not have grown on the land in the previous four years, and for Certified seed, one to two years, depending on the intervening crops. All volunteer plants and noxious weeds must be eradicated and definite boundaries to the field set before field use. Foundation seed fields must be isolated from alfalfa of different varieties by 900 feet, while Certified fields must be isolated by 165 feet. However, the 10 percent rule is followed for Certified fields, where if 10 percent or less of the Certified field is in the 165 foot isolation zone, the entire field is considered Certified, but if more than 10 percent is in the isolation zone, then that part of the field must be separated and not harvested as Certified seed. These rules are followed by most states.

Seed purity standards vary slightly across states, but remain high, especially for Foundation seed stock. As apparent in table Q-8, which shows seed purity standards for California, Idaho, Wisconsin and Montana(<http://www.idahocrop.com/standards.aspx>)( <http://www.wisc.edu/wcia/2008StandardW.pdf>)( <http://ag.montana.edu/msga/Seed%20Standards/alfalfa%20standards.pdf> ), at least 99 percent of each seed harvest must contain the pure seed variety, and there are strict limits on the allowable amounts of other crops, weeds and inert matter as well. After seed crops have been evaluated by seed labs, they are tagged with seed labels in accordance with law. Seed labs perform multiple tests mandated by the AOSCA on a representative sample from each submitted crop. All types of seed crops are accurately labeled, while Foundation and Certified seeds are denoted with a special tag. Information on the tag includes variety, kind, origin, net weight, percent pure seed, percent other materials, amount of noxious seed and weeds, and the information of the company performing the analysis (figure Q-6).

FGI has validated their Best Practices for seed production and believes they can produce seed reliably with >99.5 percent purity (FGI 2007). To put this in context, one seed in 200 could be for an off-variety, such as GT alfalfa in conventional alfalfa. Assuming that the contaminating variety has the same germination and fitness as the certified variety, then one can calculate the number of plants in an acre that would be off-type.<sup>59</sup> A thriving alfalfa hay field can have 15 plants per square foot (Orloff et al., 1997), which equals 653,400 plants in an acre; 0.5 percent of 653,400 is 3267. If the contaminating variety is mixed evenly in the seed batch, then there might be an off-type plant every 13.3 square feet. In older stands where plant density may be closer to 5 plants per square foot, there might be an off-type plant every 40 square feet. FGI's 2000 to 2002 field studies (See table Q-10), which assayed 30,000 seedlings, detected 0.000 percent gene flow (99.9 percent confidence interval is 0.01 percent), 0.01 percent contamination is 1 seed in 10,000, which is 1 plant in 667 square feet at a stand density of 15 plants per square foot.

---

<sup>59</sup> Only 60 percent of the seeds germinate and emerge and only 40 percent of emerged seedlings survive the first year (Orloff et al., 1997).

**Table Q-8. Seed Purity Standards by State**<sup>60 61 62 63</sup>

| State      | Type of Seed | Pure Seed (Min percent) | Other Crops (max percent) | Other Varieties (max percent) | Other Material (max percent) | Isolation Distance, < 5 acres (ft) |
|------------|--------------|-------------------------|---------------------------|-------------------------------|------------------------------|------------------------------------|
| California | Foundation   | 99.5                    | 0.1                       | 0.1                           | 0.5                          | 900                                |
|            | Certified    | 99.5                    | 0.1                       | 0.2                           | 0.5                          | 165                                |

### 3.7 Pollination of Alfalfa

As mentioned, alfalfa is pollinated by various insect pollinators. Hammon et al. (2007) studied alfalfa fields in Colorado, and collected data on the insects observed visiting the alfalfa. That list is in table Q-9, in order of abundance, followed by estimated ranges collected from various sources. In general, the alfalfa leafcutter bee is the preferred pollinator for alfalfa, but it is not used widely in the warmer regions of the U.S. because it has a low heat tolerance (Rogan and Fitzpatrick, 2004). Bee habits vary based on range and climate. In general, bees will forage where they need to in order to collect pollen and nectar. If there is an abundant source of both close to the nest, then their average foraging distances will be lower than if the bees must forage further to find adequate pollen and nectar. Both honey bees and alfalfa leafcutter bees will increase their foraging distance as the distance to high-reward resources (high nectar and pollen amounts) increases, and as closer resources become scarce. Patchiness of the environment also

<sup>60</sup> <http://ag.montana.edu/msga/Seed%20Standards/alfalfa%20standards.pdf>

<sup>61</sup> <http://www.idahocrop.com/standards.aspx>

<sup>62</sup> <http://www.wisc.edu/wcia/2008StandardW.pdf>

<sup>63</sup> <http://ag.montana.edu/msga/Seed%20Standards/alfalfa%20standards.pdf>

affects this foraging distance, as bees can prefer certain flowers over others (depending on the species and season), and might need to travel through or around obstacles in the environment, so they will adapt foraging habits accordingly (Greenleaf et al., 2007).

**Table Q-9. Pollinator Foraging Distance**

| <b>Pollinator (Species)</b>                           | <b>Forage Distance from Nest</b>                                                                                                             |
|-------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------|
| Alfalfa leafcutter bee ( <i>Megachile rotundata</i> ) | 300-600 feet (McCaslin et al., 2000)                                                                                                         |
| Honey bee ( <i>Apis mellifera</i> )                   | Measured up to 6.21 miles away, average distance depends on availability of pollen/nectar, typically 1.86 miles (Beekman and Ratnieks, 2000) |
| Alkali bee ( <i>Nomia melanderi</i> )                 | Will forage up to 4 or 5 miles away; typical pollination within 2 mile radius (USGS, 2008)                                                   |
| Long-horned bee ( <i>Melissodes</i> sp)               | Data not found                                                                                                                               |
| Mud/Digger bee ( <i>Anthophora</i> spp) (2)           | Data not found                                                                                                                               |
| Bumblebee ( <i>Bombus morrisoni</i> )                 | Data not found                                                                                                                               |
| Bumblebee ( <i>Bombus griseocollis</i> )              | Data not found                                                                                                                               |
| Sweat bee ( <i>Lasioglossum sisymbrii</i> )           | Data not found                                                                                                                               |
| Sweat bee ( <i>Halictus tripartitus</i> )             | Data not found                                                                                                                               |
| Sweat bee ( <i>Halictus confusus</i> )                | Data not found                                                                                                                               |
| Leafcutter bee ( <i>Megachile texana</i> )            | Data not found                                                                                                                               |
| Mason bee ( <i>Osmia laticulcata</i> )                | Data not found                                                                                                                               |

Cane (2002) performed a study on the primary pollinators of alfalfa and measured their pollination effectiveness. Alfalfa has a mechanical trip for pollination, where once the bee lands on the flower, the mechanical pressure releases the stamen and pistils, which then fly up and either deposit pollen on the bee's underside or picks up pollen if the bee has already visited another alfalfa flower. This is an irreversible process, so one visit is enough for pollination to occur. However, because honey bees dislike getting hit by the flower, they often cheat by approaching the flower from the side to get nectar, which does not pollinate the flower. This accounts for the varying pollination rates of different bee species. Females of the alfalfa leafcutter bee and the alkali bee are the most effective pollinators, tripping 81 and 78 percent of flowers visited, respectively. Males of these species are less effective, with efficiencies of 61 and 51 percent, respectively. Honey bees trip only 22 percent of flowers visited.

Agricultural farmers manipulate bee colonies to control pollination of their crops. Alfalfa farmers purposely stock bees only in seed farming, as they do not want pollination of hay fields, and because most regions that cultivate alfalfa seed do not have naturally occurring populations of alfalfa pollinators, farmers must produce, introduce and manage these pollinators to ensure pollination (Rogan and Fitzpatrick, 2004). Alfalfa leafcutter bees, a typical managed species, are established next to the target crop of alfalfa. The release of these bees can be controlled by directing incubation temperatures, which signal the bee developmental processes. Farmers judge when blooming of the crop will be at a peak, and will time the incubation and subsequent release of the bees accordingly. See section 3.4 for discussion of the interaction between flowering time and pollination, for both hay and seed fields. Once the released bees have completed their season and die, the larvae laid throughout the season are collected and cleaned, then stored at a temperature that keeps them in a pupating stage until the desired release time next year. Honey bee colonies, however, are moved from field to field as they are highly portable and stay with their queen. They also tend to forage at much larger distances, and this increases the chances of pollen being spread from one location to another. Table Q-10 presents factors that influence bee

activity (adapted from Greenleaf et al., 2007; Strickler and Vinson, 2000;  
<http://www.beeepollination.com/growers.php>).

**Table Q-10. Factors That Influence Bee Activity**

| <b>Factor</b>                     | <b>Description</b>                                                                                                                                                                            |
|-----------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Weather (rain, wind, cloud cover) | Honey bees do not fly in rain or in wind over approx. 15 mph, and have less activity on cloudy days                                                                                           |
| Temperature                       | There is a minimum temperature for bees to forage at, usually about 55°F for honey bees                                                                                                       |
| Season                            | Bees forage at specific times in the season based on species; some bees forage throughout the late spring, summer and early fall while others might only forage for a few weeks in the summer |
| Flower availability               | Bees will forage further from the nest in order to reach high reward flowers                                                                                                                  |
| Time of day                       | Bees used for alfalfa pollination typically only forage during the day                                                                                                                        |
| Hive placement                    | Hives placed at the edges of fields will pollinate the field in a different pattern than if they are placed in the middle of a field                                                          |
| Number of bees                    | If there are too many bees at a field and competition is too high, bees may leave the field to establish new colonies or nests                                                                |
| Flower biology                    | The number of days flowers are in bloom can affect pollination efficacy—the longer flowers bloom, the more chances for pollination                                                            |
| Plant competition                 | Bees will preferentially forage on more attractive flowers if given the option                                                                                                                |
| Strength of colony                | Strong colonies (higher numbers) have more flying bees and will forage in lower temperatures than weak colonies                                                                               |
| Disease and parasites             | Infected colonies and bees will forage less than uninfected colonies and bees                                                                                                                 |

### *3.7.1 Pollen Viability in the Environment*

For bees whose hives are moved between fields throughout a season, there is a question of whether viable pollen could survive in the hive and be transported. Pollen environmental viability has been tested for the wind pollinated forage grass, tall fescue (Wang et al., 2004). Pollen viability is highly sensitive to environmental conditions. This particular study examined differences between transgenic pollen and non-transgenic pollen, which were non-significant. There is an optimal temperature peak (approx 25°C or 77°F), above and below which the pollen viability decreases. Both types of pollen dropped to 5 percent viability in 30 minutes in sunny conditions, while they dropped to the same level in 150 minutes in cloudy conditions (figure Q-7a). In growth chamber conditions with controlled temperature and humidity, both types of pollen decreased to about 5 percent viability in 12 hours, with a complete loss of viability after 22 hours (figure Q-7b). This rapid decrease of pollen viability in ambient atmospheric conditions is also found in wheat (none after 65-70 min), triticale, a wheat-rye hybrid (none after 110-120 min) and maize (none after 120 min). From these data it appears that if honey bee hives are transported more than two hours away, residual pollen would be unviable in the new environment. The degree to which tall fescue and alfalfa have pollen with similar longevity is unknown. In general pollen is only viable for hours or days in the environment (Mallory-Smith and Zapiola, 2008). The FGI Best Practices do not permit hives to be moved from GT alfalfa to non-GT alfalfa within a growing season.

**Figure Q-7: Pollen longevity in tall fescue (Wang et al., 2004)**

Figure Q-7a: Longevity of pollen of tall fescue under ambient atmospheric conditions. Pollen was collected from seed-derived plants and transgenic progenies of tall fescue, and germination was evaluated under sunny (Sunny/nontransgenic, Sunny/transgenic) and cloudy (Cloudy/nontransgenic, Cloudy/transgenic) conditions.

Figure Q-7b: Longevity of pollen of tall fescue under controlled conditions (24°C, relative humidity 54 ± 5 percent) in a growth chamber as measured by percentage germination (means ± 1 SE). Pollen was collected from seed-derived plants (nontransgenic) and transgenic progenies (transgenic) of tall fescue. (Wang, 2003)

### 3.7.2 Honey Production

Alfalfa honey makes up one-third of the annual production of U.S. honey, and there is a market for organic honey. Because honey bees are known to forage over long distances, there is a chance that honey bees would bring pollen containing GT trait back to honey-producing hives if there was a GT alfalfa field nearby (Hubbard 2008).

## 3.8 Gene Flow Between Alfalfa Populations

Gene flow is a measure of exchange of genes between populations. The concern is how much gene flow is occurring between populations of GT alfalfa and non-GT alfalfa. Some farmers may want very low (<0.5 percent) or zero presence of the GT trait in their crops in order to meet the needs of their customers. This section discusses each of the nine possible combinations of gene flow between the three classes of alfalfa populations (table Q-11).

There are several factors that influence the probability of gene flow between fields (adapted from Putnam 2006):

- Probability of synchronous flowering (e.g., the percentage of days where synchronous flowering occurs).
- Availability of pollen (e.g., the percentage of bloom during each day of synchronous flowering).
- Pollinator activity on days of synchronous flowering and placement of bee hives (e.g., influenced by timed bee release and weather).
- Distance between fields (alfalfa populations).
- Probability of seed maturation.
- Probability of seed germination.

In the following sections, each of the above factors is discussed within the context of each of the nine gene flow scenarios. A summary of the research on gene flow in alfalfa is presented in table Q-11.

**Table Q-11. U.S. Research on Gene Flow in Alfalfa**

| Location                                                                         | Researcher Affiliation                | Dates            | Alfalfa Populations            | Pollinators                                                                         | Publications                                                                    |

\* both locations had both seed and hay fields as pollen sources

### 3.8.1 Seed to Seed Gene Flow

As discussed in section 3.6, there are standards in place that ensure >99 percent (Certified) and >99.9 percent (Foundation) purity for seed varieties. The mean seed yield in Nebraska and Kansas were 72 and 100 lbs per acre (1988-1992) versus greater than 500 lbs per acre for states

in prime seed growing states (Hower et al., 1999). In the 2006 growing season FGI commercial seed fields averaged 500 to 1100 pounds per acre (FGI, 2007). The factors that influence seed to seed gene flow are as follows:

- Probability of synchronous flowering – Seed fields flower for about 5-6 weeks (Bosch and Kemp, 2005). The FGI Best Practices for seed production does not mention whether flowering is intentionally offset between seed fields. Because of the length of time alfalfa can flower, there will likely be some overlap between flowering time among seed fields.
- Availability of pollen – Seed fields are allowed to go to 100 percent bloom, so pollen is available.
- Pollinator activity on days of synchronous flowering and placement of bee hives – Bee activity is managed in seed fields. Wild bees are present, but at much lower levels than the bees that are brought in for pollination.
- Distance between fields (alfalfa populations) – Refer to section B.6 for the distances between fields that are recommended for seed fields to reduce pollen flow. FGI Best Practices requires 900 feet when leafcutter bees are used, 1 mile when alkali bees are used, and 3 miles when honeybees are the predominant pollinator species (FGI 2007).
- Probability of seed maturation – Although 100 percent of the flowers that are pollinated do not mature, in seed fields most of the pollinated flowers produce mature seed. This is in contrast to hay fields, which are mowed before seed is allowed to mature.
- Probability of seed germination. – Orloff et al. (1997) state that about 60 percent of seeds germinate when planted under good conditions (correct depth and soil conditions). When a hay farmer plants commercially produced seed the germination rate is indicated on the label. This assumes that the field has been properly prepared and the soil is free of herbicides and alfalfa autotoxic compounds.

#### 3.8.1.1 Summary of Research – Seed to Seed

Armand et al. (2000) examined gene flow from both alfalfa hay and seed fields to outside populations (trap plots), and the differences between small and large source populations. Their results indicate that pollen does not travel far within a field, with dispersal distances of 4 meters or less. This could indicate that the bees are being cleansed of marker pollen by visiting non-marker plants close by, as opposed to depositing marker pollen far away. At 1,000 meters (3,281 feet), up to 22.2 percent of the trap population seed was from outcrossing (possibly more as the 1,000 meter populations were the farthest examined). Also, a higher amount of gene flow was found when the source population was a large field as opposed to a small study population, and the marker was exchanged between escaped alfalfa populations. A summary of Armand et al (2002) data is reproduced in figure Q-8. It should be noted that the trap populations Armand et al. (2000) used were clonal and therefore likely to have a high degree of self-incompatibility. Self-incompatibility within the clonal trap population would lead to seeds being formed more frequently from outcrossing from the source field. The clonal traps may not represent how feral alfalfa would receive pollen, since feral populations would pollinate among themselves and thus be less receptive to distant pollen sources (Rogan and Fitzpatrick, 2004). The clonal nature of the trap plots was because the researchers identified a unique marker gene in a single plant and

bred several generations to develop homozygous plants for the marker band. GT alfalfa varieties and conventional varieties do not have as high degree of genetic similarity as the research line created by Armand et al. (2000).

• **Figure Q-8: Summary data from Armand et al. (2000)**

Gene movement away from commercial-scale (large) seed and hay production fields and research-scale (small) seed and hay plots in Kansas and Washington State. Progeny from trap plots of cloned alfalfa were examined for a specific marker-gene and for apparent non-self events using RAPDs. Outcrossing from small plots was not detected beyond 200 m (note axis scale change)

FGI's 2000 to 2002 field studies using leafcutter bees, in Idaho, showed a range of 1.39 percent (1.72 percent is the 99.9 percent confidence level upper limit) at 500 feet and 0.0000 percent (0.01 percent CI) at  $\frac{3}{4}$  of a mile (Fitzpatrick et al., 2002). Table Q-12 and figure Q-9 present a summary of these field studies.

**Table Q-12. Summary of FGI Idaho Gene Flow Studies (Fitzpatrick et al., 2002)**

Table Q-12. Isolation distance between trap and source, number of replicates per distance, replicate plot size (acres), trap plot cardinal direction from source and, interplot land cover <sup>a,b,c</sup>, the mean observed gene flow and the upper bound of true gene flow (i.e., the 99.9% confidence interval upper limit) are given.  
Interplot land cover: <sup>a</sup> Various crop species typical for the area (e.g., onions, corn, wheat, etc.); <sup>b</sup> roadways, or <sup>c</sup> fallow. “-” indicates distance not tested.

**Figure Q-9: Summary of GFI 2000-2002 gene flow studies (Rogan and Fitzpatrick 2004)**

Three-year summary of alfalfa gene flow for seed production using leafcutter bees with 150 ft to 1 mile isolation distance from gene source plot. Values given are the observed and upper bound of true gene flow (99.9% confidence) based on all data collected during 2000, 2001, and 2002 field studies. The equation for,  $Y_{Ci} = (4 \times 10^6)(X^{-2.3673})$  was calculated using seed production source plots only. USDA Notification Numbers: 00-053-07n (2000); 01-009-08n (2001); 02-020-09n (2002).

University of California—Davis, FGI and Monsanto studied seed to seed gene flow using honey bees (2003 growing season). At 900 feet gene flow was 1.49 percent, near 5,000 feet it was 0.2 percent, and at 2.53 miles it was  $\leq 0.06$  percent (Teuber et al., 2004). Gene flow was estimated by growing seeds from the trap plots and testing the seedlings for glyphosate tolerance (75,000 to 90,000 seedlings were tested per trap plot). Seed samples from the 2003 field study were also

tested using the transgene protein detection strip test. The strip test results were in agreement with the large scale seedling growout assays (Teuber et al., 2007).

In 2006 and 2007, in the San Joaquin Valley of California, a mixed honey bee and leafcutter bee gene flow study was done (Teuber et al., 2007; Van Deynze et al., 2008). A summary data from those studies is presented in table Q-13.

**Table Q-13. Seed to Seed Gene Flow (Teuber et al., 2007)**

| <b>Distance</b> | <b>Gene Flow (percent adventitious presence)</b> |
|-----------------|--------------------------------------------------|
| 165 feet        | 2.3                                              |
| 900 feet        | 0.9                                              |
| 4,000 feet      | 0.6                                              |
| 1 mile          | 0.2                                              |
| 3 miles         | 0.03                                             |
| 5 miles         | Not detected                                     |

During the 2006 growing season, FGI conducted a study to validate their FGI Best Practices (FGI 2007). They tested 122 of their conventional commercially-grown seed lots. Of the 122 lots, 115 of the lots were grown in a region containing at least one GT alfalfa seed field at a know isolation distance and 32 of the lots had detectable gene flow. In the lots where gene flow was detected, it was at the low level of 0.004 to 0.180 percent. Experimental plots were also set up to capture gene flow that occurs at distances less than recommended by FGI Best Practices. The data from this study are presented in table Q-14.

**Table Q-14. Summary of FGI Commercial-scale Seed Production Gene Flow Study (FGI 2007)**

| Distance from source field (feet, x) | Small conventional fields with worse-case setting for gene flow |                                                            |                                                        | Large conventional fields grown under commercial-practice settings |
|--------------------------------------|-----------------------------------------------------------------|------------------------------------------------------------|--------------------------------------------------------|--------------------------------------------------------------------|
|                                      | Predicted gene flow (%) at < 1 mile isolation <sup>c</sup>      | Predicted gene flow (%) at > 1 mile isolation <sup>d</sup> | Observed gene flow in test plots (%) <sup>a or b</sup> | Observed gene flow (%) in FGI commercial fields                    |
| 50                                   | 1.84                                                            |                                                            |                                                        |                                                                    |
| 165                                  | 1.80                                                            |                                                            | 1.96 <sup>b</sup>                                      |                                                                    |

Analysis of honeybee-mediated gene-flow (%) between adjacent alfalfa seed fields predicted using two linear models developed from research trial data presented by Teuber et al. (2005) and data observed in 2003<sup>a</sup> and in 2006<sup>b</sup> experiments. "Small" (≤2.2 acre) or "large" conventional seed fields were separated from Roundup Ready alfalfa seed fields at a range of isolation distances (165 feet to more than 10 miles). In 2003 and 2006 experiments, each individual conventional trap plot was 11 or 150 times smaller than the Roundup Ready pollen source plot, respectively. Also in the experimental plots, isolation was compromised ("bridged") for all but shortest distance by other alfalfa trap seed plots stocked with honeybee hives at commercial density. Combined, these biases favored maximum Roundup Ready gene flow and allowed for measurement and modeling of pollen-mediated gene flow under "worse-case situations". In contrast, in the 2006 commercial-practice "large" seed fields true isolation was used and the conventional and Roundup Ready seed fields were approximately equal in size (non worse-case). Gene flow potential using cultured honeybee pollination, commercial seed grower practices and 1 mile true isolation resulted in approximately three to five times less gene flow than predicted using worse-case models.

<sup>a</sup> 2003 Data published previously in Teuber et al., 2004 and 2005, % observed in bioassay test. These data values were used by Teuber et al. (2005) to calculate the linear regression models for honeybees, given below.

<sup>b</sup> 2006 Data developed by Teuber et al., unpublished, preliminary data; % estimated from laboratory test; these fields did not conform to Best Practices isolation by experimental design.

<sup>c</sup> Predicted values for <1 mile were calculated per Teuber et al. 2005 linear regression model:  $y = -0.00030x + 1.8529$ ,  $x^2 = 0.98$ , where y is % gene flow and x is distance (ft.)

<sup>d</sup> Predicted values for >1 mile were calculated per linear regression model calculated using the data published by Teuber et al. 2005 data for distances >1 mile:  $y = -0.00012x + 1.2143$ ,  $r^2 = 0.72$ ,  $p = 0.02$  (significant fit).

<sup>e</sup> 2006 Data developed by FGI from commercial seed fields; these FGI-owned conventional seed fields were grown to conform to FGI Best Practices

In summary, the largest data set collected under actual seed production conditions, using FGI Best Practices, found a range of gene flow from 0.00 to 0.18 percent. This is well below the FGI company goal of less than 0.5 percent adventitious presence.

### 3.8.2 Hay to Seed Gene Flow

Hay to seed gene flow is another possible source of presence of the GT trait in non-GT alfalfa seeds. The factors that influence hay to seed gene flow are as follows:

Probability of synchronous flowering – Seed fields flower for about 5-6 weeks (Bosch and Kemp, 2005). Hay fields that are harvested at 10 percent bloom only have flowers for about a week (Shroyer et al., 1984) and for most of that time the field is at far below 10 percent bloom.<sup>64</sup> There may be some overlap between flowering time among hay fields and seed fields, but it is likely to be limited to a few days (figure Q-3).

Availability of pollen from hay fields – Hay fields may be harvested any time between pre-bud and 100 percent bloom; however the majority of fields are harvested at or below 10 percent bloom.

Pollinator activity on days of synchronous flowering and placement of bee hives – Bees are brought in for seed fields, but not for hay fields. Wild bees are present at relatively low levels compared to bees brought in for seed field pollination. There will likely be some bee activity in hay fields with bloom, especially if bee hobbyists have hives nearby.

Distance between fields (alfalfa populations) – There are no required distances between hay fields, but seed fields are still required to be separated from hay fields (section 3.6).

Probability of seed maturation – Although 100 percent of the flowers that are pollinated do not mature, in well cared for seed fields most of the pollinated flowers produce mature seed. This is in contrast to hay fields, which are mowed before seed is allowed to mature.

Probability of seed germination. – Orloff et al. (1997) state that about 60 percent of seeds germinate when planted under good conditions (correct depth and soil conditions). When a hay farmer plants commercially produced seed the germination rate is indicated on the label. This assumes that the field has been properly prepared and the soil is free of herbicides and alfalfa autotoxic compounds.

#### 3.8.2.1 Summary of Research – Hay to Seed

Table Q-6 (Armand et al., 2000) presents hay to seed data. Refer to section 3.8.1 for discussion of Armand et al (2000).

In field studies in 2002, in Washington, FGI detected 0.21 percent gene flow at 150 feet and 0.23 percent gene flow at 300 feet. The hay fields which were the source of pollen were mowed at 50 percent bloom (Teuber and Fitzpatrick, 2007; Rogan and Fitzpatrick, 2004). Figure Q-10 presents this hay to seed in the same graph as the seed to seed data that FGI collected in the same time period in Idaho. A larger scale hay to seed gene flow study by the same researchers, but performed in the San Joaquin Valley of California, in 2006, yielded the data presented in table Q-15. Hay was harvested at 20 percent bloom and seed fields had been stocked with honey bees.

---

<sup>64</sup> Maturity timeline varies based on environmental conditions. However, Shroyer et al. (1984) present a figure with alfalfa progressing from bud to 1/10 bloom in one week.

**Table Q-15. Hay to Seed Gene Flow (Teuber and Fitzpatrick, 2007)**

| Distance between hay and seed field (feet) | Percentage gene flow |
|--------------------------------------------|----------------------|
| 165                                        | 0.29                 |
| 215                                        | 0.16                 |

**Figure Q-10: Hay to seed gene flow (Teuber and Fitzpatrick 2007)**

Observed gene flow (Y %) from hay field plots growing near replicated alfalfa seed field plots in 2000 (▲) and 2006. These trials simulated delayed harvest of hay fields growing near and beyond the AOSCA certified seed field isolation standard (i.e., 165 ft). In 2000, replicated hay plots in Washington were allowed to mature to 50% flower (5X the optimum hay cut stage), seed field plots were stocked with leafcutter bees and separated by 150 or 300 ft from the Roundup Ready® hay field plot<sup>2</sup>. In 2006, replicated seed field plots at the University of California were allowed to mature to 20% flower (2X the optimum hay cut stage), seed field plots were stocked with honeybees and separated by 165 to 615 ft from the Roundup Ready hay field plot.

In summary, hay to seed gene flow is less likely than seed to seed gene flow because hay fields do not usually have more than 10 percent bloom, and that is only for a few days. In addition, certified and foundation seed fields are required to have specific distances between them and other alfalfa fields. There are some farmers that grow uncertified seed which could be immediately adjacent to GT alfalfa hay fields thus GT alfalfa could cross pollinate with conventional alfalfa.

### 3.8.3 Feral to Seed Gene Flow

Many seed farmers control feral alfalfa that may be growing near their seed fields. The factors that influence feral to seed gene flow are as follows:

- Probability of synchronous flowering – Seed fields flower for about 5-6 weeks (Bosch and Kemp, 2005). Feral alfalfa blooms as environmental growth conditions permit. There may be some overlap between flowering time among feral alfalfa and seed fields.

- Availability of pollen from feral alfalfa – Feral alfalfa, if not managed (mowed), and if environmental conditions permit, will flower. Environmental stresses such as drought and insects may greatly reduce flower formation compared to cultivated alfalfa.
- Pollinator activity on days of synchronous flowering and placement of bee hives – Bees are brought in for seed fields and may also visit feral alfalfa if the hives are close enough to the feral populations. Bees may prefer other flowering wild species growing with feral alfalfa, which could reduce bee visits to feral alfalfa. Wild bees are present at relatively low levels compared to bees brought in for seed field pollination. There will likely be some bee activity in feral alfalfa populations and those bees may also visit alfalfa seed fields.
- Distance between seed fields and feral alfalfa – If seed farmers properly manage feral populations, then there should be a sufficient distance between feral populations and seed fields to achieve the current goals of seed purity. Seed farmers will need to be aware of seeding practices in neighboring rangelands because falcata (yellow-flowered alfalfa) may become increasingly adopted for rangeland forage improvement. Falcata seed is available commercially (<http://www.windriverseed.com/Website%20catalog.pdf>).
- Probability of seed maturation – Although 100 percent of the flowers that are pollinated do not mature, in well cared for seed fields most of the pollinated flowers produce mature seed.
- Probability of seed germination – Orloff et al. (1997) state that about 60 percent of seeds germinate when planted under good conditions (correct depth and soil conditions). When a hay farmer plants commercially produced seed the germination rate is indicated on the label. This assumes that the field has been properly prepared and the soil is free of herbicides and alfalfa autotoxic compounds.

No studies that specifically addresses feral to seed gene flow were identified.

#### 3.8.4 *Seed to Feral Gene Flow*

The factors that influence seed to feral gene flow are as follows:

- Probability of synchronous flowering – Seed fields flower for about 5-6 weeks (Bosch and Kemp, 2005). Feral alfalfa blooms as environmental growth conditions permit. There may be some overlap between flowering time among feral alfalfa and seed fields.
- Availability of pollen from seed fields – Seed fields have the highest amount of available pollen compared to the other two populations of alfalfa (hay and feral). Farmers manage field conditions (water and insect control) to maximize flower formation.
- Pollinator activity on days of synchronous flowering and placement of bee hives – Bees are brought in for seed fields. Wild bees are present at relatively low levels compared to bees brought in for seed field pollination. There will likely be some bee activity in the feral populations, especially if bee hobbyists have hives nearby.
- Distance between seed fields and feral alfalfa – If seed farmers properly manage feral alfalfa, there should be very little feral alfalfa to receive pollen. Seed farmers will need to be aware of seeding practices in neighboring rangelands because falcata (yellow-flowered alfalfa) may become increasingly adopted for rangeland forage improvement. Most rangeland farmers will not be sensitive to the presence of GT alfalfa growing on their

rangeland, however there may be organic beef and dairy farmers who will want their rangeland to be free of the presence of the GT trait.

- Probability of seed maturation – If genetic compatibility and the health of the plant are sufficient then feral seeds will mature. Because feral alfalfa is under environmental stresses, such as insect predation and drought that are managed in seed fields, feral alfalfa is likely to have a much lower seed yield than plants in seed fields. If feral alfalfa is mowed, then it will have a much reduced likelihood of maturing.
- Probability of seed germination. – If seed is not set, germination is irrelevant. Germination near parent plants is limited by the autotoxicity of alfalfa. Seeds of many plant species, including alfalfa, are spread through the feces of wildlife and other grazing animals (personal communication Gerald Schuman, retired USDA ARS, July 30, 2008).

#### 3.8.4.1 Summary of Research – Seed to Feral

Hammon et al. (2007) harvested feral alfalfa plants from 23 sites within two miles of GT alfalfa seed fields near Fruita, Colorado. The GT transgene was found at 83 percent of the collection sites out to a distance of 1.7 miles. Figure Q-11 shows the gene flow recorded by Hammon et al. (2007).

**Figure Q-11: Seed to feral gene flow (Hammon et al., 2006)**

#### 3.8.5 Feral to Feral Gene Flow

The factors that influence feral to feral gene flow are as follows:

- Probability of synchronous flowering – Feral alfalfa blooms as environmental growth conditions permit. There is evidence of naturalized alfalfa populations that are over 80 years old (Smith, 1997), so it is clear that feral populations have some level of

synchronous blooming even under rangeland grazing conditions. Very small feral populations may have less synchronous blooming, unless the environment (including soil conditions) promotes synchronous blooming.

- Availability of pollen – Feral alfalfa, if not managed (mowed), and if environmental conditions permit, will flower. Environmental stresses such as drought and insects may greatly reduce flower formation compared to cultivated alfalfa.
- Pollinator activity on days of synchronous flowering and placement of bee hives – Pollination within and between feral populations depends on wild pollinators, unless hobbyists' honey bee hives are nearby. There may also be some bee activity from hives brought in for seed fields. The presence of bees for pollinating remote feral populations is much lower than for feral populations that are near seed fields and other farming operations that utilize managed bee hives.
- Distance between feral populations – Feral populations may be so remote that they do not interbreed. Kendrick et al. (2005) surveyed feral alfalfa at 940 sites in six states. Feral alfalfa populations along roadsides were one to greater than 12 miles apart.<sup>65</sup>
- Probability of seed maturation – If genetic compatibility and the health of the plant are sufficient then feral seeds will mature. Because feral alfalfa is under environmental stresses, such as insect predation and drought that are managed in seed fields, feral alfalfa is likely to have a much lower seed yield than plants in seed fields. If feral alfalfa is mowed, then it will have a much reduced likelihood of maturing.
- Probability of seed germination. – If seed is not set, germination is irrelevant. Germination near parent plants is limited by the autotoxicity of alfalfa. Seeds of many plant species, including alfalfa, are spread through the feces of wildlife and other grazing animals (personal communication Gerald Schuman, retired USDA ARS, July 30, 2008).

### 3.8.5.1 Summary of Research – Feral to Feral

Armand et al. (2000) placed feral trap plants along roadsides and in urban areas at least 800 meters from known alfalfa fields. Feral to feral gene flow was detected at 230 meters, but not in any of the urban sites. Table Q-16 summarizes Armand et al. (2000) feral to feral gene flow data.

**Table Q-16. Feral to Feral Gene Flow (Armand et al., 2000)**

| Sample                                                                  | Isolation Distance (meters) <sup>a</sup> | Total Seeds Tested | Outcrossing Frequency Percent |
|-------------------------------------------------------------------------|------------------------------------------|--------------------|-------------------------------|
| Escape #1                                                               | 70                                       | 22                 | 90.9                          |
| Escape #2                                                               | 79                                       | 20                 | 80.0                          |
| Escape #3                                                               | 145                                      | 15                 | 46.7                          |
| Escape #4                                                               | 230                                      | 51                 | 92.2                          |
| Urban #1                                                                | >800                                     | 0 <sup>b</sup>     | NA                            |
| Urban #2                                                                | >800                                     | 0 <sup>b</sup>     | NA                            |
| Urban #3                                                                | >800                                     | 0 <sup>b</sup>     | NA                            |
| <sup>a</sup> Distance to the nearest individual alfalfa plant or field. |                                          |                    |                               |
| <sup>b</sup> No seed set in urban areas.                                |                                          |                    |                               |

If a gene is introduced to a population at a low frequency, then it will begin to move towards an equilibrium frequency in the population. In general, genes at low frequencies in populations

<sup>65</sup> For a review of Kendrick et al. (2005) see the Technical Report Effects of Glyphosate-Tolerant Weeds in Non-Agricultural Ecosystems

undergoing random mating experience genetic drift, which can push an allele out of a population. (Genetic drift is the change in gene frequencies due to random chance. For example, if one plant out of 100 has the GT gene, then gene flow is at one percent, but if that plant happens to be eaten by a deer, then the frequency of the gene in the population randomly changed to 0 percent). However, if the gene imparts a selective advantage, then natural selection will act to maintain the gene in the population. The GT trait is not expected to impart increased fitness in feral alfalfa. If there is high gene flow between populations, then even if a gene is pushed out of a population by a force such as drift, then it could be reintroduced again at a later time (Scott, 2007). The GT trait has not been shown to have a fitness cost and herbicide resistance transgenes have been shown to persist in *Brassica napus* and *Brassica rapa* hybrids under field conditions, even though the hybrids themselves had a fitness penalty (Mallory-Smith and Zapiola, 2008). The frequency of the GT trait in feral alfalfa populations after introduction would be based on a balance between these factors.

### 3.8.6 Hay to Feral Gene Flow

The factors that influence hay to feral gene flow are as follows:

- Probability of synchronous flowering – Hay fields that are harvested at 10 percent bloom only have flowers for about a week (Shroyer et al., 1984) and for most of that time the field is at far below 10 percent bloom. Feral alfalfa blooms as environmental growth conditions permit. There may be some overlap between flowering time among feral alfalfa and hay fields.
- Availability of pollen – Hay fields may be harvested any time between pre-bud and 100 percent bloom; however the majority of fields are harvested at or below 10 percent bloom.
- Pollinator activity on days of synchronous flowering and placement of bee hives – Wild bees and hobbyist bee hives are the sources of pollinators between hay and feral populations.
- Distance between fields (alfalfa populations) – Out of all the alfalfa populations, feral and hay populations are likely to be the closest the most often. Hay farmers do not typically control feral alfalfa, and much of the feral alfalfa near hay fields is escaped hay seed, which may not persist as a breeding population. Kendrick et al. (2005) surveyed feral alfalfa populations in six states at 940 sites. In Idaho, feral and cultivated populations occurred within 2000 meters of each other in approximately three sites per county. In approximately half of those sites, the average distance was less than 20 meters. In Wisconsin, three-fourths of the sites where feral and cultivated populations occurred together had an average distance of less than 20 meters. In California, feral and cultivated populations occurred within 2000 meters of each other in approximately six sites per county. In approximately half of those sites, the average distance was less than 20 meters.
- Probability of seed maturation – If the health of the plant is sufficient then feral seeds will mature. Because feral alfalfa is under environmental stresses, such as insect predation and drought that are managed in seed fields, feral alfalfa is likely to have a much lower

seed yield than plants in seed fields. If feral alfalfa is mowed, then it will have a much reduced likelihood of maturing.

- Probability of seed germination – If seed is not set, germination is irrelevant. Germination near parent plants is limited by the autotoxicity of alfalfa. Seeds of many plant species, including alfalfa, are spread through the feces of wildlife and other grazing animals (personal communication Gerald Schuman, retired USDA ARS, July 30, 2008).

No studies that specifically address hay to feral gene flow were identified.

### *3.8.7 Seed to Hay Gene Flow*

Hay fields have the lowest probability of producing seed compared to feral plants and seed fields. Regardless of the any cross-pollination that happens, hay fields are unlikely to produce seed, therefore they are the lowest risk of propagating gene flow. The factors that influence seed to hay gene flow are as follows:

- Probability of synchronous flowering – Seed fields flower for about 5-6 weeks (Bosch and Kemp, 2005). Hay fields that are harvested at 10 percent bloom only have flowers for about a week (Shroyer et al., 1984) and for most of that time the field is at far below 10 percent bloom. There may be some overlap between flowering time among hay fields and seed fields, but it is likely to be limited to a few days (figure Q-3).
- Availability of pollen – Seed fields have the highest amount of available pollen compared to the other two populations of alfalfa (hay and feral). Farmers manage field conditions (water and insect control) to maximize flower formation.
- Pollinator activity on days of synchronous flowering and placement of bee hives – Bees are brought in for seed fields, but not for hay fields. Wild bees are present at relatively low levels compared to bees brought in for seed field pollination. Seed farmers maximize pollinator activity within seed fields. Bees brought into seed fields do visit nearby hay fields.
- Distance between fields (alfalfa populations) – There are no required distances between hay fields, but seed fields are still required to be separated from hay fields (section 3.6).
- Probability of seed maturation – Mowing during early bloom basically eliminates the chances of seed set. If there are marginal areas of the field that escape mowing, those plants can be considered part of the escaped feral population. Hay fields that are intentionally left to set seed are considered seed fields. Sometimes farmers harvest a few crops of hay, then a crop of seed from the same field. Farmers growing GT alfalfa are prohibited from this practice, unless they have a seed grower contract with FGI and follow FGI Best Practices.
- Probability of seed germination – If seed is not set, germination is irrelevant. In the case that some small amount of seed does set in a hay field, then germination is limited by the autotoxicity of alfalfa.

No studies that specifically address seed to hay gene flow were identified. This is because any study that potentially addressed seed to hay gene flow did not mow the hay. Studies where trap plants were allowed to mature and set seed are not accurate representations of hay fields.

### 3.8.8 *Feral to Hay Gene Flow*

The factors that influence hay to seed gene flow are as follows:

- Probability of synchronous flowering – Feral alfalfa blooms as environmental growth conditions permit. Hay fields that are harvested at 10 percent bloom only have flowers for about a week (Shroyer et al., 1984) and for most of that time the field is at far below 10 percent bloom. There may be some overlap between flowering time among hay fields and feral populations, but it is likely to be limited to a few days.
- Availability of pollen – Feral alfalfa, if not managed (mowed), and if environmental conditions permit, will flower. Environmental stresses such as drought and insects may greatly reduce flower formation compared to cultivated alfalfa.
- Pollinator activity on days of synchronous flowering and placement of bee hives – Wild bees and hobbyist bee hives are the sources of pollinators between hay and feral populations.
- Distance between feral populations and hay fields – Out of all the alfalfa populations, feral and hay populations are likely to be the closest the most often. Hay farmers do not typically control feral alfalfa, and much of the feral alfalfa near hay fields is escaped hay seed, which may not persist as a breeding population. (See section 3.8.6 for description of Kendrick et al., 2005)
- Probability of seed maturation – Mowing during early bloom basically eliminates the chances of seed set. If there are marginal areas of the field that escape mowing, those plants can be considered part of the escaped feral population. Hay fields that are intentionally left to set seed are considered seed fields. Feral populations should be managed near seed fields and hay fields that are occasionally harvested as seed fields.
- Probability of seed germination. – If seed is not set, germination is irrelevant. In the case that some small amount of seed does set in a hay field, then germination is limited by the autotoxicity of alfalfa.

### 3.8.9 *Hay to Hay Gene Flow*

The factors that influence hay to hay gene flow are as follows:

- Probability of synchronous flowering – Adjacent hay fields will bloom at the same time if the variety of alfalfa is similar, planting schedules are similar and the growing conditions are similar. Irrigation inputs, fertilization inputs, and pest management (weeds, insects, small mammals, and diseases) can influence the maturity of alfalfa hay.
- Availability of pollen – Hay fields may be harvested any time between pre-bud and 100 percent bloom; however the majority of fields are harvested at or below 10 percent bloom.
- Pollinator activity on days of synchronous flowering and placement of bee hives – Bees are brought in for seed fields, but not for hay fields. Wild bees are present at relatively low levels compared to bees brought in for seed field pollination. There will likely be some bee activity in hay fields with bloom, especially if bee hobbyists have hive nearby.

- Distance between hay fields (alfalfa populations) – There are no required distances between hay fields.
- Probability of seed maturation – Mowing during early bloom basically eliminates the chances of seed set. If there are marginal areas of the field that escape mowing, those plants can be considered part of the escaped feral population. Hay fields that are intentionally left to set seed are considered seed fields. Sometimes farmers harvest a few crops of hay, then a crop of seed from the same field. Farmers growing GT alfalfa are prohibited from this practice, unless they have a seed grower contract with FGI and follow FGI Best Practices.
- Probability of seed germination. – If seed is not set, germination is irrelevant. In the case that some small amount of seed does set in a hay field, then germination is limited by the autotoxicity of alfalfa.

No studies that specifically address hay to hay gene flow were identified. However Putnam (2006) provided an estimate based on probabilities which are included in figure Q-12. Gene flow between seed and hay fields is summarized in figure Q-12 from Van Deynze et al. (2008).

**Figure Q-12: Gene flow likelihood (Van Deynze et al., 2008)**

#### *Conditions Increasing Probability of Gene Flow*

As the above sections indicate, there are multiple factors involved in studying the impact of GT alfalfa. Factors have the potential to increase gene flow between crops include, but not limited to, the following:

- Feral alfalfa creates gene flow corridors — If feral alfalfa grows between fields of GT alfalfa and non-GT alfalfa, then it could provide a corridor for gene flow between these fields. It could act as a stepping stone for pollinators that would be more likely to travel between flowers that are closer together than between distant fields.
- A pest management strategy currently in practice is that of leaving a strip of uncut alfalfa during hay harvest, which can act as a reserve for both insect pests and beneficial pollinators. If these alfalfa strips are GT alfalfa, and are not ever cut, they would have the chance to flower and seed. This would result in a the risk of pollinator-mediated spreading of the GT trait to nearby established feral populations, and could mean that the chance of gene flow from hay fields to other fields can be just as great as the chance of gene flow from seed fields to other fields. (Mueller 2005).
- Seed field proximity can increase gene flow between the fields. The seed fields are generally found in a compact geographic area, and with pollinators that have the potential to forage over miles (honey bees; for instance), this creates a potential for cross fertilization in non-GT alfalfa seed fields. (Hubbard 2008)
- As with any agricultural crop, there is the possibility of volunteer alfalfa growing in the field during other crop rotations. If these volunteer plants were GT, then normal glyphosate-based herbicide routines would not eradicate them, creating a possibility that the volunteer plants would flower, set seed, and be a source of pollen for gene flow (Altieri, 2001). Also, alfalfa produces “hard seeds”, seeds whose hard coating prevents moisture from germinating the seed. It is possible that these seeds can remain dormant from one season to the next, and then germinate at a later time, creating the possibility of the presence of GT alfalfa even after alfalfa is no longer produced in a field (Hubbard, 2008).
- Movement of honey bees from crop to crop could increase the chance of transferring pollen from one field to another.
- Release of too many bees to pollinate one field by farmers can lead to far dispersal of the bees. Bees will respond to the competition at that one field, and then will forage further to find nectar and pollen or to establish nests at alternate sites. This might happen before they visit any flowers of the target field, or they might visit the target field before traveling, increasing the risk of gene flow from the target field (which may be GT alfalfa) to other fields (possibly non-GT alfalfa) (Bosch and Kemp, 2005).

### *3.8.13 Conditions Decreasing Probability of Gene Flow*

FGI and Monsanto have developed stewardship programs to address concerns regarding gene flow (FGI 2007).<sup>66</sup> Seed growers undergo training and have to be licensed to grow GT alfalfa seed. Any farmer who purchases GT alfalfa seed for producing hay is required to sign a Monsanto Technology/Stewardship Agreement (MTA). The FGI Best Practices for seed growers is the primary mechanism for limiting gene flow. Features of the MTA and FGI Best Practices are as follows:

---

<sup>66</sup> The stewardship programs also address other concerns such as weediness potential and glyphosate resistant weed formation.

- GT alfalfa seed producers may not sell seed to any party other than FGI and growers may not save seed for any purpose.
- Bee hives cannot be moved out of GT alfalfa until pollination is finished for the year. This prevents pollen being carried via hive between GT and non-GT alfalfa. Grower must indicate main pollinator species on the FGI Seed Grower Contract.
- Isolation through distance from other alfalfa fields is required. For pollination with leafcutter bees the distance must be greater than or equal to 900 feet, for Alkali bees greater than or equal to one mile, for honey bees greater than or equal to three miles.
- FGI reports seed field location and planting date to local seed certifying organizations, which GMO-sensitive farmers can refer to in order to certify isolation distances.
- Stand removal and volunteer management must be sufficient to allow seed certification inspectors to validate stand removal. Stand removal date and method must be reported to FGI and verified.
- Cleaning requirements for equipment are included in the FGI Best Practices.
- The Monsanto MTA requires hay growers to harvest at or before 10 percent bloom.
- The Monsanto MTA states that GT alfalfa hay growers are not allowed to produce seed off of hay fields.

Additional factors that could decrease the potential for gene flow include:

- Barriers between fields – Types of barriers can include bodies of water, or other, more attractive plants for bee foraging in between fields. A border of plants at field edges has the benefit of being a buffer zone, as pollen would be deposited in the border population before leaving a GT alfalfa field. If the border were also alfalfa, this would ensure that pollinators would not preferentially avoid the border area. However, the border would need to be treated as GT alfalfa, and if it starts out as non-GT alfalfa, then the spread of genes from that population to the GT alfalfa could adversely affect the cultivation of GT alfalfa seeds by reducing seed purity. If the border were not alfalfa, but a different plant, this would prevent bees from traveling far from the field, and fewer GT genes would be spread. However, this could be difficult if the border plant has different growing and management requirements from the alfalfa, or if it is an attractive plant to pollinators, which would discourage the alfalfa pollinators from pollinating the alfalfa, and could encourage distant bees to forage there, increasing long-distance pollen flow. Seeds produced by a non-alfalfa plant could also contaminate the purity of the alfalfa seed crop. (Amand, et al., 2000; Rogan and Fitzpatrick, 2004)
- Competition with existing plants is difficult for volunteer alfalfa plants that must establish themselves and compete for nutrients against adult plants.

#### *3.8.14 Modeling Gene Flow*

GENESYS is a modeling program that allows the simulation of gene flow between crops, based on cropping systems and other parameters (Colbach et al., 2001a, 2001b). Given the available data and variables for entire cropping systems in a region, cropping systems that would minimize the potential of gene transmission and dispersal can be identified (along with those of high dispersal potential). This program has previously been used to evaluate the potential of transmission of herbicide-tolerant genes from rapeseed crops to rapeseed volunteers, and can be

adapted and applied to other crops. It can also analyze the effect of cropping systems on the genetic evolution of the crop.

- Parameters that are used in the model include (Dzeroski et al., 2006):
- The field plan of the region, comprising cultivated fields and field-edges or borders consisting of spontaneous vegetation;
- The crop rotation of each field;
- The cultivation techniques applied to each crop (intercrop cultivation, soil tillage, sowing date and density, herbicide applications, cutting dates and seed loss at harvest);
- The type of the transgene, either a dominant allele *A* or recessive *a*, as well as the genotype of the crop varieties.

The more accurate and complete the parameters entered into the model are, the more accurate the results of the model will be. The model output is the level of GE seed present in conventional crops. The model can also identify key variables that are most influential on gene dispersal. This model could be adapted to predict alfalfa gene flow; however it may not be necessary because FGI has obtained actual gene flow data from commercial scale seed production (FGI 2007).

A Gene Flow Index (GFI) ranking scheme has been developed for sugar beet, oilseed rape, potato, perennial ryegrass, maize, wheat, and barley (Mullins 2005). This index could be used to put alfalfa in perspective to other GE crops.

### 3.9 Summary of Findings

Alfalfa is a perennial crop, pollinated by alfalfa leafcutter bees (*Megachile rotundata*), honey bees (*Apis mellifera*), and alkali bees (*Nomia melanderi*), and it is cultivated primarily for hay (forage) or seed. Because it is pollinated by insects, pollen and gene flow between different alfalfa fields is possible. This is an issue when a proportion of cultivated alfalfa is GT alfalfa, and growers of non-GT alfalfa wish to prevent the entry of GT traits in their seed stocks and crops.

For hay farmers, the quality of the hay is dependent on nutrient content, which is linked to the maturity of the plants at harvest, both of which are predicted by the amount of bloom present at harvest. The nutrient content of hay is tested before sale price is determined. The earlier the harvest, the better quality the hay is. It is often recommended to harvest hay when it is at one-tenth bloom. It is important to know the level of bloom present in alfalfa hay fields in order to gauge the possibility of pollen flow between the fields or from hay fields to seed fields. Alfalfa hay production occurs mainly in the West and Northwest United States, and while California produces the most hay in the country in pounds, South Dakota has the most hay acreage.

Seed farmers are concerned with the purity of their seed stock, and follow state and Federal-mandated standards in order to produce seed of certified purity. Isolation distances between fields and threshold amounts of allowable off-types of seed vary by state, but in general, seed stock must be 99 percent of the variety or varieties stated on the label. Alfalfa seed production

also occurs mainly in the West and Northwest United States, and California produces the most seed in the country, in both pounds and acreage.

Pollination of alfalfa is highly dependent on the species of pollinator used. Honey bees have been known to forage over 6 miles from their nests, while alfalfa leafcutter bees only forage 300-600 feet from their nests. Female alfalfa leafcutter and alkali bees are the most effective alfalfa pollinators, pollinating 81 and 78 percent of visited flowers, respectively. Honey bees only pollinate 22 percent of visited flowers. Alfalfa seed farmers manipulate bee colonies in order to ensure pollination of their fields, and release of pollinators influences the duration of flowering in alfalfa fields. The more bees released at one time, the quicker the flowers stop blooming, and flower availability and number of bees can impact pollen transport. Other factors that affect bee activity and therefore affect pollination include weather, season, time of day, hive placement, plant competition, strength of the colony and disease.

Given proper adherence to FGI Best Practices and Monsanto's MTA the risk of cross-fertilization is well below FGI's goal of less than 0.5 percent presence. Gene flow between and into seed fields is of higher concern than gene flow into hay fields. This is primarily because hay fields are mowed before seed is set, so even if pollen with GT trait arrives at a non-GT hay field, propagation of seed is unlikely. Feral alfalfa is a concern if it is not managed near seed fields. Feral alfalfa near GT alfalfa hay fields may receive GT trait, but the trait's survival in the feral population depends on whether there is selection pressure to maintain the trait and chance. The GT trait is not expected to enhance feral alfalfa fitness. Rangeland alfalfa (*falcata*) populations may be growing as ranchers intentionally seed *falcata* into rangeland to increase forage quality and soil nitrogen. The impact of GT alfalfa on rangeland *falcata* is unstudied.

## 4.0 Glyphosate-Tolerant Alfalfa Presence in Food or Animal feed

Human food uses of alfalfa are minor, with majority of alfalfa consumed by humans as freshly sprouted seedlings (sprouts) or as compressed leaf material in dietary supplements or herbal teas. In efforts to assess the human health and livestock risks of exposure to the GT alfalfa gene, gene product, transgene, and glyphosate will be evaluated in this report.

Monsanto Company and Forage Genetics International, jointly developed GT alfalfa, designated as events J101 and J163 that were genetically engineered for tolerance to the herbicide glyphosate (Roundup®). The possibility of these GE varieties being present in food and feed supplies and the importance of the alfalfa crop, warrant a thorough assessment of the impacts, if any, of introducing the GT alfalfa crop for commercialization.

Limited data on the effects of GT alfalfa presence in human food and animal feed is available at present. However, the CP4 EPSPS gene that confers glyphosate resistance in alfalfa has been used in previous GT crops, such as soybeans, corn, canola, and wheat. Previous data on CP4 EPSPS can therefore be considered in evaluating the presence of GT alfalfa in human food and animal feed.

### 4.1 Probability of Presence

Monsanto the manufacturer of GT alfalfa does not allow GT alfalfa to be planted for sprouts (Hubbard, 2008); therefore, human exposure to GT alfalfa appears to be minimal.

### 4.2 Health Effects of CP4 EPSPS Transgene or Protein

The CP4 EPSPS transgene may pose a food safety risk for two reasons: 1) the transgene product could be toxic to humans or livestock due to direct toxicity, anti-nutritive effects or allergenic effects or 2) the transgene could cause a change in the metabolic pathways of the crop altering levels of pre-existing metabolites or introducing new metabolite(s). The U.S. Food and Drug Administration (FDA), the lead U.S. regulatory agency for review of the food and feed safety of GE crops, completed a voluntary consultation with FGI and Monsanto in 2004 regarding the GT alfalfa (US FDA, 2004b). The FDA's safety assessment of the gene product, CP4 EPSPS protein, concluded that Roundup Ready® alfalfa is safe for consumption by humans and animals (US FDA, 2004b).

#### *4.2.1 Health Effects of cp4 epsps Transgene on Humans*

The CP4 EPSPS was found to be readily degraded by digestive juices and based on amino acid sequence homology searches, shown to be structurally or functionally unrelated to any known protein allergens or toxins. Transgene products associated with GT crops have been shown to have no allergenic properties. Sten et al. (2004), in a study with soybean-sensitized patients, found that the allergenicity of ten glyphosate-tolerant and eight non-transgenic soybean cultivars were not different. Chang et al. (2003) found no significant allergenicity to rats of the CP4 EPSPS gene product conferring glyphosate resistance.

#### *4.2.2 Health Effects of cp4 epsps Transgene on Livestock*

The persistence of plant-derived recombinant DNA in sheep and pigs fed genetically engineered (GT) canola was assessed by Sharma et al. (2006) utilizing Polymerase Chain Reaction (PCR) and Southern hybridization analysis of DNA extracted from digesta, gastrointestinal (GI) tract tissues, and visceral organs. This study confirmed that feed-ingested DNA fragments (endogenous and transgenic) do survive to the terminal GI tract and that uptake into gut epithelial tissues does occur. A very low frequency of transmittance to visceral tissue was confirmed in pigs, but not in sheep. There was no evidence to suggest that recombinant DNA would be processed in the gut in any manner different from endogenous feed-ingested genetic material.

The nutritional safety of a similar GT maize line GA21 was evaluated by Sidhu et al. (2000) in a poultry feeding study. Results from this study showed that there were no significant differences in growth, feed efficiency, adjusted feed efficiency, and fat pad weights between chickens fed with GA21 grain or with parental control grain.

#### *4.2.3 Health Effects of cp4 epsps Transgene on Forage Bees*

The CP4 EPSPS transgene is similar to the gene that is normally present in alfalfa and is not known to have any toxic property. Field observations of events J101 and J163 revealed no negative effects on non-target organisms. The lack of known toxicity for this enzyme suggests no potential for deleterious effects on beneficial organisms such as bees and earthworms.

#### *4.2.4 Health Effects of cp4 epsps Transgene on Non-livestock Animals (Wildlife)*

No specific data or scientific literature was found relating to the health effects of the CP4 EPSPS Transgene on non-livestock animals. The *cp4 epsps* gene contained in GT crops is similar to other members of the EPSPS family of genes that are common in the environment. Therefore, there is no evidence the *cp4 epsps* gene will exhibit adverse biological activity towards wildlife.

#### *4.2.5 Health Effects of CP4 EPSPS Protein on Humans*

The novel CP4 EPSPS protein present in glyphosate-tolerant alfalfa J101 and J163 has been assessed previously for safety in approved lines of canola, cotton, soybean, and corn. Previous assessments have shown that CP4 EPSPS administered directly to animals at a high dose is not toxic, and the evidence indicates no potential for this protein to be allergenic in humans (FSANZ, 2006).

#### *4.2.6 Health Effects of CP4 EPSPS Protein on Livestock*

Coombs and Hartnell (2007) fed dairy cows GT alfalfa grown in southeastern Washington State harvested at the late vegetative state, or other conventional alfalfa harvested from the same geographic region. Milk production, milk composition, feed intake, and feed efficiency were not affected by feeding diets that contained nearly 40 percent glyphosate-tolerant alfalfa hay to

lactating dairy cows (Coombs and Hartnell, 2007). Detection of the gene or protein in milk, feces, or flesh of these cows was not performed.

In another dairy cow study, GT corn or non-GE corn was consumed (Ipharraguerre et al., 2003). The production of milk, quality of milk, and udder health were unaffected by GT gene or protein consumption in dairy cattle.

Steer were fed GT corn or a control near isogenic parental hybrid non-GE corn diet for 144 days. Weight, feed:gain ratio, marbling, and fat composition were no different between feeding groups (Pol et al., 2003).

Glyphosate-tolerant soybean meal was fed for 3 months (172 g/kg) to post-smolt salmon (Bakke-McKellep et al., 2007). Other post-smolt salmon were fed a non-modified soy; however, this soy was non-parental soy with several differences in the levels of anti-nutritional factors. Thus the qualitative and quantitative differences in the inflammatory response observed in the distal intestine as well in the head kidney of the genetically modified soy fed salmon were due to difference in soybean variety. Further study is needed with the control group needing to be near-isogenic parental line soybeans (Bakke-McKellep et al., 2007). In addition to this, no specific data or scientific literature was found relating to the health effects of the CP4 EPSPS protein on livestock animals.

#### *4.2.7 Health Effects of CP4 EPSPS Protein on Forage Bees*

A number of researchers have conducted laboratory investigations with different types of arthropods exposed to GE crops containing the CP4 EPSPS protein (Goldstein, 2003; Boongird et al., 2003; Jamornman et al., 2003; Harvey et al., 2003). Representative pollinators, soil organisms, beneficial arthropods and pest species were exposed to tissues (pollen, seed, and foliage) from GE crops that contain the CP4 EPSPS protein. These studies, although varying in design, all reported a lack of toxicity observed in various species exposed to these crops (Dunfield and Germida, 2003, Siciliano and Germida 1999).

No effects were observed on pollen harvest behavior of workers bees, or on survival and development of honey bee egg, larvae or pupa when exposed to GT corn pollen during and after pollination (Boongird et al., 2003).

#### *4.2.8 Health Effects of Protein on Non-livestock Animals (Wildlife)*

No specific data or scientific literature was found relating to the health effects of the CP4 EPSPS protein on non-livestock animals. The CP4 EPSPS protein contained in GT crops is similar to other members of the EPSPS family of proteins that are common in the environment; thus there no evidence that the CP4 EPSPS protein will exhibit adverse biological activity towards wildlife.

### 4.3 Health Effects of Herbicide Glyphosate Residue on GT Alfalfa to Humans

Glyphosate has a complete regulatory data base (toxicity, environmental fate, and ecological toxicity) that has been evaluated by EPA to support all currently approved uses including GT alfalfa. EPA and USDA have stated that they have a high level of confidence in the quality of the existing studies and the reliability of the toxicity endpoints that are the basis for risk assessment (US EPA, 1993, 2006a, 2006b, USDA, 2003). In general, the herbicidal activity of glyphosate is due primarily to a metabolic pathway that does not occur in humans or other animals, and, thus, this mechanism of action is not directly relevant to the human health risk assessment. EPA considers glyphosate to be of low acute and chronic toxicity by the dermal route of exposure. Glyphosate is considered a Category IV dermal toxicant and is expected to cause only slight skin irritation.

Comprehensive toxicological studies in animals have demonstrated that glyphosate does not cause cancer, birth defects, mutagenic effects, nervous system effects or reproductive problems (US EPA, 1993, 2006a, 2006b, USDA, 2003; WHO/FAO, 2004). In fact, after a thorough review of all available toxicology data, the US EPA concluded that glyphosate should be classified in Group E - Evidence of Non-carcinogenicity in Humans (US EPA, 1993).

In establishing food and feed tolerances to support the use of glyphosate on animal feed and forage crops (the group tolerance that supports the use of glyphosate in conventional and GT alfalfa), EPA noted that it had conducted “a complete and thorough review of the available data for glyphosate,” and determined that “glyphosate will not pose unreasonable risks or adverse effects to humans or the environment” (US EPA, 2002<sup>67</sup>). The risk assessment process as mandated by the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) requires that any pesticide prior to the sale or distribution must be evaluated for its potential risks to humans and the environment. The process of registering a pesticide is a scientific, legal, and administrative procedure through which EPA examines the ingredients of the pesticide; the particular site or crop on which it is to be used; the amount, frequency, method and timing of application, and other conditions of its use; and storage and disposal practices. In evaluating a pesticide registration application, EPA assesses a wide variety of potential human health and environmental effects associated with use of the product.

The data required by EPA are used to evaluate whether a pesticide has the potential to cause adverse effects on humans, wildlife, fish, and plants (including endangered species and “non-target” organisms – organisms that the pesticide is not intended to act against). The registration applicant must also supply data addressing the pesticide’s potential impact on surface water or ground water (which might result from leaching or runoff, for example). Potential human health and safety risks range from short-term toxicity to long-term effects such as cancer and reproductive system disorders.

Where pesticides may be used on food or feed crops, EPA also sets tolerances (maximum pesticide residue levels) for the amount of the pesticide that can legally remain in or on foods. EPA undertakes this analysis under the authority of the Federal Food, Drug, and Cosmetic Act (FFDCA). Under the FFDCA, EPA must find that such tolerances will be safe, meaning that there is a reasonable certainty that no harm will result from aggregate exposure to the pesticide

---

<sup>67</sup> Prior to 2002, separate alfalfa forage and alfalfa hay tolerances were established for glyphosate.

chemical residue. This finding must be made and the appropriate tolerance established before a pesticide can be registered for use on the particular food or feed crop in question. Several factors must be addressed before a tolerance can be established, including:

the aggregate, non-occupational exposure from the pesticide (exposure through diet, from using pesticides in and around the home, and from drinking water);

the cumulative effects from exposure to different pesticides that produce similar effects in the human body;

whether there is increased susceptibility to infants and children, or other sensitive subpopulations, from exposure to the pesticide; and

whether the pesticide produces an effect in humans similar to an effect produced by a naturally-occurring estrogen or produces other endocrine-disruption effects.

**Table Q-17. Established Glyphosate Tolerances Prior to GT Crops (1993)**

| <b>Crop</b>       | <b>Established Food/Feed Tolerances</b>                   | <b>Publication</b> | <b>Percent of Reference Dose (RfD)</b>                                            |

| <b>Roundup Ready alfalfa</b>     | 2006                                | Establish new tolerances for alfalfa seed at 0.5 ppm.<br>Existing tolerances for alfalfa forage (400 ppm) and hay (200 ppm) were sufficient to cover new in-crop uses. | 70 FR 7861<br>Petition No. 2F6487<br>US EPA, 2005                          | Dietary exposure insignificant, did not conduct new risk assessment. Deferred to assessment conducted for flex cotton as published in 69 FR 65081. |

Residue tolerances currently established for glyphosate in or on alfalfa raw agricultural commodities are, for the most part, the same as they were prior to the approval of GT alfalfa. The use of glyphosate in GT alfalfa did not require an increase in the tolerances in either alfalfa forage or hay (US EPA, 2000), therefore no increase in animal commodity tolerances were required. In 2002, EPA included alfalfa in the animal feed, nongrass group tolerance (US EPA, 2002), so individual tolerances for alfalfa forage and hay were no longer needed. However, the postemergence use of glyphosate for the production of GT alfalfa seed did require the establishment of a new tolerance for alfalfa seed at 0.5 ppm (US EPA, 2005) to account for the

potential human exposure to glyphosate residues resulting from the inadvertent use of GT alfalfa seed in the production of alfalfa sprouts.

**Table Q-19. Aggregate Exposure Assessment for Glyphosate**

| Population Subgroup                     | Acute Aggregate <sup>2</sup> | RfD (mg/kg/day) <sup>2</sup> | Chronic Aggregate <sup>1,2</sup> |             | Short/Intermediate Term Aggregate <sup>2</sup> |             |

<sup>1</sup> Chronic aggregate exposure is the same as chronic dietary exposure because chronic non-dietary exposure is not expected based upon the current registered non-crop uses of glyphosate.

<sup>2</sup> U.S. EPA OPPTS. Glyphosate Human Health Risk Assessment for Proposed Uses on Safflower and Sunflower. Petition No. 4E6878. Sept. 5, 2006.

#### 4.4 Health Effects of Herbicide Glyphosate Residue on GT Alfalfa to Livestock

The US EPA's toxicological and ecotoxicology and fate databases on glyphosate are considered adequate and complete (US EPA, 2006a; 1993), and based on this data, glyphosate is considered to be a toxicologically and ecologically low-risk herbicide (Cerdeira and Duke, 2006). For an in depth look at the effects of glyphosate to the environment please refer to technical report *Potential Impacts To Wildlife, Amphibians, Plants, And Ecosystems From Increased Glyphosate And Other Chemical Usage* (appendix N).

#### 4.5 Health Effects of Herbicide Glyphosate Residue on GT Alfalfa to Forage Bees

Technical grade glyphosate and Roundup are slightly toxic to bees when applied orally or topically with 2-day LD<sub>50</sub> values of  $\geq 100 \mu\text{g}$  (a.i. or product) per bee. Scientific literature shows that pollen from GT canola has no adverse effects on honeybees (Huang et al. 2004).

#### 4.6 Health Effects of Herbicide Glyphosate Residue on GT Alfalfa to Non-Livestock Animals (Wildlife)

Glyphosate has not been reported to have insecticidal or other activities against terrestrial arthropods. Studies on the effects of glyphosate on spiders have shown that it is harmless to non-target arthropods (Haughton et al. 2001). No effects of glyphosate on microarthropods in soil at double the recommended application rates have been reported (Gomez and Sagardoy, 1985). No adverse effects of glyphosate on the fecundity and fertility of green lacewings have been reported and the glyphosate formulation - Sting SE, has been documented to have no adverse impact on the food uptake and mortality of the beetle *Poecilus* (IPCS-INCHEM, 1994).

No adverse effects on earthworms have been reported with the use of glyphosate. With an LC<sub>50</sub> value of > 5,000 parts per million (ppm) (Ahrens 1994), glyphosate has been ranked zero on a scale of zero (nontoxic) to four (extremely toxic) for its toxicity to earthworms (Edwards and Bohlen 1996). Glyphosate formulations on the other hand (Roundup and Roundup D-pak) are slightly toxic to earthworms with 14-day NOEC values of 500 and 158 mg product per kg dry weight, respectively.

For an in depth look at the effects of glyphosate to the environment please refer to technical report *Potential Impacts To Wildlife, Amphibians, Plants, And Ecosystems From Increased Glyphosate And Other Chemical Usage* (appendix N).

#### 4.7 Summary of Findings

The use of glyphosate herbicide does not appear to result in adverse effects on development, reproduction, or endocrine systems in humans and other mammals. Under present and expected conditions of use, glyphosate herbicide does not pose a health risk to humans. There is little evidence of any direct effect of glyphosate on arthropods in the field or in natural environments. The higher toxicity of glyphosate to aquatic invertebrates can mainly be attributed to the presence of surfactants.

Current weight-of-evidence from similar GE crops (Peterson, 2005) suggests that the transgenic CP4 EPSPS protein present in GT alfalfa poses negligible risk to humans, livestock, and wildlife. Most studies available in scientific literature support the view that food from GT crops is substantially equivalent to non-transgenic crops.

## Appendix Q-2. Literature Search

### 5.0 Literature Search Strategy

#### 5.1 Purpose

The purpose of this literature search is to locate references about the presence of human and animal feed due to GT alfalfa as well as health and safety implications.

We propose that the following DIALOG databases be included in the search:

The following DIALOG databases will be included in the search:

|                                    |                                                 |
|------------------------------------|-------------------------------------------------|
| File 5: BIOSIS                     | File 117: Water Resources Abstracts             |
| File 6: NTIS                       | File 144: PASCAL                                |
| File 10: AGRICOLA                  |                                                 |
| File 34: SciSearch                 | File 154: MEDLINE                               |
| File 41: Pollution Abstracts       | File 156:ToxFile                                |
| File 40: Enviroline                | File 245: WATERNET™                             |
| File 72: EMBASE                    | File 250: CAB Abstracts                         |
| File 76: Environmental Sciences    | File 266: Federal Research In Progress (FEDRIP) |
| File 79: Aqualine                  | File 399: CA SEARCH®: Chemical Abstracts®       |
| File 98: General Science Abstracts |                                                 |

Descriptions of these files are available at <http://library.dialog.com/bluesheets/>.

#### 5.2 Scope of Search

The search will focus any published references after 1990. A reference list with abstracts will be screened for relevance to fermentation processes. English language only publications will be retrieved.

The following list will be retrieved and expanded upon.

#### 5.3 Strategy Overview

A list of search parameters is listed below.

#### 5.4 Synonyms

|                                 |                                     |
|---------------------------------|-------------------------------------|
| Glyphosate                      | <i>N</i> -(phosphonomethyl) glycine |
| Glyphosate, isopropylamine salt | Roundup®                            |
| Glyphosate, sodium salt         | Rodeo®                              |
|                                 | Honcho®                             |

Glyphosate, potassium  
Glyphosate, ammonium  
Glyphosate, sulfosate

## 5.5 Keywords

|                        |                     |
|------------------------|---------------------|
| Acute                  | Health effect(s)    |
| Alfalfa                | Ingest*             |
| Allowable daily intake | Leach*              |
| Chronic                | Metabo*Occupational |
| Contaminat*            | Persistence         |
| Crop                   | Residue             |
| Degradation            | Risk                |
| Detect*                | Tolerance           |
| Dietary risk           | Toxic*              |
| Emission               | Usage patterns      |
| Environmental impacts  |                     |
| Exposure(s)            |                     |

## 5.6 Submission of Citations for Approval

Using reference management software, pooled information obtained from the various bibliographic databases will be screened to remove duplicates. Additionally, ICF will review the list prior to submission and eliminate any irrelevant citations. Information will include the following (when available):

Author(s). Publication Year. Title. Source Document Name, Volume, Page Numbers.  
Abstract  
Descriptors/Identifiers (*i.e.*, keywords and subject headings)

Search Terms for Gene Flow Appendix

Google

**Appendix R:       Impacts to United States Trade of  
Deregulation of Glyphosate-Tolerant  
Alfalfa**

# **Impacts to United States Trade of Deregulation of Glyphosate-Tolerant Alfalfa**

## **Executive Summary**

U.S. exports of alfalfa hay and processed alfalfa are considerably concentrated in Japan, and U.S. exports of alfalfa seeds have increasingly gone to Saudi Arabia. Japan and South Korea are the world's largest importers of forage and Saudi Arabia is the largest importer of alfalfa seed, after the United States.

Saudi Arabia will not import glyphosate-tolerant (GT) alfalfa seeds. There is no evidence, however, that Saudi Arabia will not continue to import non-GT U.S. alfalfa seed as long as exporters are able to guarantee seed purity standards.

There is evidence that Japan may decrease its imports of non-GT alfalfa hay from the United States with GT alfalfa deregulation. This seems to be motivated mainly by businesses concerned with negative reactions from consumers, even in the absence of labeling requirements in downstream dairy and meat products.

U.S. imports of alfalfa hay and seed come mostly from Canada. To the extent that GT alfalfa deregulation reduces foreign demand for U.S. exports, alfalfa hay and seed production previously destined to foreign markets may be channeled to the domestic market. As the domestic market for non-GT alfalfa hay and seed is expected to decrease with GT alfalfa deregulation, U.S. production is likely to substitute imports.

## 1.0 Introduction

### 1.1 Scope of Report

This report analyzes impacts to United States trade of deregulation of glyphosate-tolerant (GT) alfalfa.

### 1.2 Methodology

Analysis of the potential impact of deregulation of GT alfalfa on U.S. trade was divided into its impact on U.S exports and its impacts on U.S. imports. Exports and imports of alfalfa seed, alfalfa hay and processed alfalfa are examined. We also look at exports of downstream products such as dairy and meat.

On several occasions the analysis in the present Technical Report makes use of conclusions drawn from our previous Technical Reports *Economic and Social Impacts to Conventional and Organic Farmers of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix S), and *Downstream Effects to Organic Production and Marketing of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix T).

Section 2 of this report analyzes exports and section 3 looks at imports. As in previous Technical Reports, we explain our bibliographic search methods in appendix R-2 of this technical report. In appendix R-3 of this technical report, we make a few considerations on how foreign trade impacts on the county level analysis that was done in previous reports.

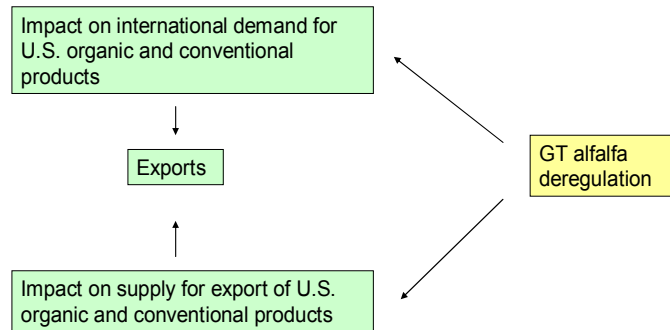

#### 1.2.1 Assumptions

The impact of GT alfalfa deregulation on international demand for U.S. exports stems from the availability of GT alfalfa in the U.S. market, potentially generating perceptions by foreign clients that U.S. exports of non-GT alfalfa and animal products produced from non-GT alfalfa fed livestock may contain GT alfalfa. How this would affect demand depends on a) whether there is any GT sensitivity among foreign clients for U.S. alfalfa; and b) how clients react to potential unintended presence. There may be no impact on demand at all, or markets may distinguish between GT alfalfa and non-GT alfalfa, as well as between products made from animals fed with GT alfalfa and non-GT alfalfa, with different conditions for acceptance in each of these markets (market segmentation).

On the side of the U.S. supply for exports, the impact of GT alfalfa deregulation will depend on the capacity of U.S. producers to meet their clients' demands and whether this capacity comes at a higher cost than before.

The figure below illustrates the cause-effect links to be analyzed.

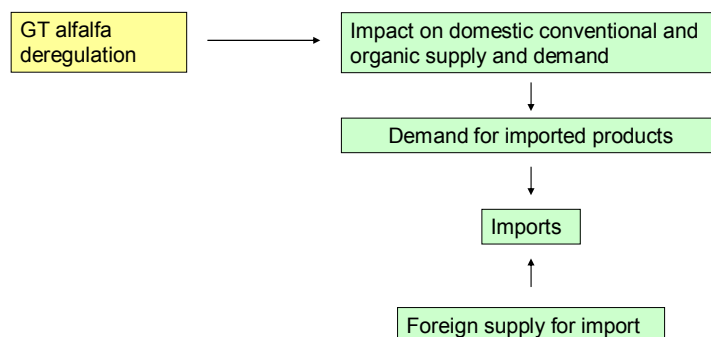

For:  
 1) Alfalfa seed  
 2) Alfalfa hay and processed alfalfa  
 3) Dairy, beef, livestock and pet care products

**Figure R-1: Deregulation impact on exports**

Impacts on imports may occur if GT alfalfa deregulation increases or decreases the need of domestic markets for imports or the costs of domestic products competing with imports. This would affect U.S. demand for imported alfalfa and derived products. We illustrate with the figure below.

For:  
 1) Alfalfa seed  
 2) Alfalfa hay and processed alfalfa  
 3) Dairy, beef, livestock and pet care products

**Figure R-2: Deregulation impact on imports**

### *1.2.2 Data and Information Sources*

Most U.S. trade data was obtained from USDA's Foreign Agriculture Service that reports exports and imports since 1989 as classified under the U.S. 10 digit Harmonized System and compatible with the World Customs Organization's 6 digit Harmonized System. Trade data was typically report up to 2007, to be consistent with the domestic information from the 2007 Census of Agriculture. Trade data as reported by the US Harmonized System does not discriminate for organic products.

For trade data for other countries we made use of foreign government data sources or the United Nations' Commodity Trade Statistics Database (Comtrade).

Data was complemented with information obtained from articles, typically of an academic nature and peer-reviewed whenever possible, under the assumption that these documents are subject to standards that should help reduce if not eliminate any intentional bias.

## 2.0 Impacts on Exports

### 2.1 Trends

#### 2.1.1 Alfalfa Seed

Data on alfalfa seed exports is provided by USDA Foreign Agricultural Service (FAS) through its U.S. Trade Internet System (FASonline). Saudi Arabia has been the largest export market of U.S. alfalfa seed after passing Argentina, having increased its purchases significantly in 2006 and doubling in size in 2007. Other important markets in Mexico, Canada, and Argentina have fluctuated but remain at similar levels over the five year period. Data for the first six months of 2008 suggests Saudi Arabia's major purchases continue (\$14,801,000 in January – June of 2008). Table R-1 shows the size of the major export markets over a six-year period.

**Table R-1. U.S. Exports of Alfalfa Seed, \$1000**

|              | 2002   | 2003   | 2004   | 2005   | 2006   | 2007   |
|--------------|--------|--------|--------|--------|--------|--------|
| Saudi Arabia | 7,533  | 13,523 | 11,659 | 12,233 | 17,172 | 38,075 |
| Mexico       | 6,600  | 8,636  | 9,652  | 9,955  | 10,018 | 9,578  |
| Argentina    | 2,837  | 3,300  | 7,682  | 6,793  | 5,521  | 5,062  |
| Canada       | 2,081  | 2,867  | 4,294  | 5,573  | 5,042  | 2,960  |
| Other*       | 6,912  | 10,674 | 10,685 | 10,404 | 7,389  | 10,379 |
| Total        | 25,963 | 39,000 | 43,972 | 44,958 | 45,142 | 66,054 |

Source: USDA, FAS (FASonline). Code 120921 of the US Harmonized Tariff System; \*Includes Japan, China, and Peru, among others.

FASonline does not provide price data for the different export markets. However, by comparing quantities imported to the value of the export market, table R-2 shows value per metric ton of exported U.S. alfalfa seed. Saudi Arabia not only purchases the most U.S. alfalfa seeds, it also pays the highest price.

**Table R-2. U.S. Exported Alfalfa Seed, \$ value per Metric Ton**

|              | 2002   | 2003  | 2004  | 2005  | 2006  | 2007  |

Source: USDA FAS (FASonline). Code 120921, value of export / quantity of export.

#### 2.1.2 Alfalfa Hay and Processed Alfalfa

Total U.S. exports of alfalfa hay grew considerably between 1998 and 2002 but then stabilized somewhat in export value, while likely declining in quantities<sup>68</sup>. Japan is by far the main destiny of U.S. alfalfa hay exports, followed by South Korea and Taiwan. Japan's share of U.S. exports

<sup>68</sup> FASonline, reports quantities traded of the "greatest number of like units of measure for grouped commodities." To the extent that this reflects total quantities of alfalfa hay exported, there has been a decline in exports in recent years.

has fallen in recent years (but still at 68% of total) with an important growth of exports to South Korea. Table R-3 shows the growing value of U.S. alfalfa hay exports.

**Table R-3. U.S. Alfalfa Hay Exports, \$1000**

|         | 1998   | 1999    | 2000    | 2001   | 2002    | 2003    | 2004    | 2005    | 2006    | 2007    |
|---------|--------|---------|---------|--------|---------|---------|---------|---------|---------|---------|
| Japan   | 77,882 | 84,405  | 77,527  | 66,705 | 114,749 | 120,994 | 136,193 | 125,663 | 120,791 | 115,888 |
| S.Korea | 3,560  | 6,499   | 17,915  | 18,437 | 22,590  | 21,888  | 19,974  | 19,979  | 25,318  | 31,778  |
| Taiwan  | 4,182  | 5,223   | 3,668   | 5,010  | 10,237  | 7,866   | 7,891   | 9,646   | 10,647  | 11,563  |
| Other*  | 5,344  | 4,978   | 4,770   | 5,675  | 5,993   | 7,600   | 7,476   | 9,801   | 8,436   | 12,020  |
| Total   | 90,965 | 101,104 | 103,879 | 95,827 | 153,569 | 158,348 | 171,533 | 165,087 | 165,192 | 171,249 |

Source: USDA FAS (FASonline). Code 1214900010 of the U.S. Harmonized Tariff System; \*Includes Mexico and Canada, among others.

Woodward (2006) notes that demand for imported alfalfa hay from Japan and South Korea, the two major export markets for U.S. alfalfa hay, has steadily increased. Milk production has remained stable in both countries and livestock production has declined but this has been offset by declines in forage production in these countries. Japan has seen a decrease in forage production of 17 percent, and South Korea has faced a decline of 53 percent, maintaining the demand for imported alfalfa hay steady.

The above numbers do not include processed hay into meal and pellets. U.S. exports of meal and pellets, dehydrated or sun cured, in cubes or other form, were in 2007 approximately \$30 million. In the last 10 years, exports of processed alfalfa decreased about 30 percent (1998 to 2007). However, during that time total processed alfalfa exports experienced fluctuations between -34 percent (between 2000 and 2001) and 27 percent (between 2002 and 2003), as illustrated in table R-4. These fluctuations can be attributed primarily to Japan, the largest importer of U.S. processed alfalfa, with on average 87 percent of the U.S. export market over the past decade. In the years described above, Japan experienced fluctuations as high as 25 percent (2002-2003) and as low as -24 percent (2000-2001).

**Table R-4. U.S. Processed Alfalfa Exports, \$1000**

|         | 1998   | 1999   | 2000   | 2001   | 2002   | 2003   | 2004   | 2005   | 2006   | 2007   |
|---------|--------|--------|--------|--------|--------|--------|--------|--------|--------|--------|
| Japan   | 41,189 | 33,672 | 26,684 | 20,328 | 25,667 | 32,086 | 26,233 | 24,736 | 20,734 | 23,169 |

| Total   | 42,792 | 36,291 | 33,776 | 22,343 | 27,348 | 34,646 | 30,839 | 28,702 | 24,349 | 30,392 |

Source: USDA, FAS (FASonline). Code 121410 of the U.S. Harmonized Tariff System; \*Includes Mexico and the United Arab Emirates, among others.

United States seems to be steadily losing market share in its exports of alfalfa hay and in cubes to its main buyer, Japan. In the ten years in which Japan's total forage imports increased by 18.5 percent, exports of U.S. forage only increased by 7.5 percent. Although Canada's share of this market has remained stable, Australia's share grew 800 percent from 1995 to 2004 (Woodward, 2006). Table R-5 shows how Australia's exports grew significantly from accounting for less than 3 percent of imported alfalfa hay and cubes in Japan to be the second largest supplier of that country. During the same period, U.S. market share fell from over 81% to just over 70%.

**Table R-5. Share of Japan Export Market for Alfalfa Hay and Cubes (% by tonnage)**

|           | 1995  | 1996  | 1997  | 1998  | 1999  | 2000  | 2001  | 2002  | 2003  | 2004  |
|-----------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|
| USA       | 81.64 | 80.90 | 80.68 | 77.74 | 78.22 | 77.83 | 77.21 | 74.86 | 77.16 | 70.01 |
| Australia | 2.29  | 4.17  | 5.11  | 5.62  | 7.01  | 7.96  | 8.67  | 12.39 | 13.54 | 16.50 |
| Canada    | 13.18 | 11.73 | 10.62 | 13.17 | 11.73 | 12.83 | 13.41 | 12.12 | 8.66  | 12.97 |
| China     | 2.43  | 2.79  | 2.88  | 2.85  | 2.49  | 0.66  | 0.02  | 0.03  | 0.19  | 0.19  |

Source: Woodward, 2006

Most of the U.S. loss in market share is accounted for by hay. The U.S. share of Japan's alfalfa cube imports actually increased over the same period from 74 percent in 1995 to 87 percent in 2004. This gain in market share for alfalfa cubes is largely accounted for by a significant decline in Canadian alfalfa cube exports to Japan while Australian exports fluctuated without steadily increasing (Woodward, 2006).

### *2.1.3 Dairy, Beef, Livestock and Pet Care Products*

Exports of dairy, beef, livestock, and pet care products are downstream markets of alfalfa production. Particularly relevant is the dairy market, that consumes a major share of alfalfa hay produced in the United States and that has seen foreign markets become increasingly important for U.S. dairy producers, with 9.5 percent of all U.S. dairy production in 2007 exported (USDEC, 2007). The export value of dairy products grew by 357 percent from 1998 to 2007. A large part of this increase in exports went to Mexico, which remains the largest importer of U.S. dairy products. The U.S. Dairy Export Council (USDEC) predicts these increases to continue as further tariffs are lifted under the North American Free Trade Agreement (NAFTA). Table R-6 shows U.S. dairy product exports to the top importing nations.

**Table R-6. U.S. Dairy Product Exports, \$1000**

|          | 1998    | 1999    | 2000    | 2001    | 2002    | 2003    | 2004      | 2005      | 2006      | 2007      |

Unlike foreign dairy markets, U.S. exports of meat and edible offal remained relatively stable since 2000, with an increase, however, in 2007 (table R-7).

**Table R-7. U.S. Meat and Edible Offal Exports, \$1000**

|        | 2000      | 2001      | 2002      | 2003      | 2004      | 2005      | 2006      | 2007      |

## 2.2 Impacts of GT Alfalfa Deregulation

There is considerable heterogeneity among countries on regulation pertaining to genetically engineered (GE) food and feed (Gruère G. P., 2006). While most countries lack any regulations at all, the main U.S. markets for alfalfa and downstream products do have regulations. These regulations involve food safety approval processes, labeling, or both.

Of all regions, the European Union has arguably the most stringent regulations. GE food and feed must be approved for safety. Once approved, labeling is required even if there are no detectable GE traits in the final product, as long as GE products were intentionally used in the production process. For foods and feed where no GE products were intended, a traceability process must be implemented throughout the chain whenever potential GE content exists and labeling is required for any presence of GE material above 0.9% of total content. Both

traceability and labeling imply considerable costs to producers (Gruère G. P., 2006; Gruère G. P. and Rao S. R., 2007). Animal products such as meat, dairy and eggs, however, are exempt of such labelling and traceability requirements.

Japan, Saudi Arabia and South Korea, main alfalfa export markets, all have approval processes for GE products and labeling requirements.

### *2.2.1 Standards in Main Export Markets*

The approval of GE foods in Japan is the responsibility of the Ministry of Health, Labor and Welfare (MHLW). MHLW has zero tolerance for unapproved GE foods and conducts inspection and testing of cargoes arriving in Japan, inspecting up to 50% of all cargoes (Gruere, 2006). Monsanto's J101 and J163 have completed MHLW's approval process (MHLW, 2008).

Approval of GE feed is the responsibility of the Ministry of Agriculture, Fisheries and Forestry (MAFF). A one per cent threshold for presence of GE content in feed is allowed as long as the GE product has been approved by the exporting country and the exporting country is considered to have safety assessments equivalent to Japan's (Gruere G. P., 2006).

Labeling is mandatory for all GE foods as long as GE content can be detected, the GE ingredient is one of the first three ingredients of a product, and accounts for more than five percent of the total weight (Gruere G. P., 2006). Unlike the labeling requirements of the European Union, labeling requirements are based only on product content and not process (Gruère G. P. and Rao S. R., 2007).

South Korea has similar approval processes and labeling requirements as Japan: the Ministry for Food, Agriculture, Forestry and Fisheries (MFAFF) regulates labeling for unprocessed GE products while the South Korea Food and Drug Administration (KFDA) regulates food safety and labeling of processed foods. As of July 2008, South Korea had approved 54 biotech products, including Monsanto's J101 x J163 Alfalfa (USDA FAS, 2008a).

Labeling in South Korea is mandatory for unprocessed GE food and for unprocessed non-GE food containing more than three percent presence of GE material. In the case of processed foods, labeling is required if the GE ingredient is among the top five and is detectable in the final product. GE animal feed must also be labeled (USDA FAS, 2008a). Processed food with non detectable levels of GE material, such as dairy, meat and vegetable oils do not require labeling.

Taiwan requires labeling for products containing more than 5% GE content of (USTR, undated).

For alfalfa seed, the most important export market is Saudi Arabia. Although the country allows imports of labeled GE variety grains and plant/vegetable processed foodstuffs, imports of GE variety seeds have been banned since 2004 (FAS, 2007a).

Mexico, the main downstream export market for dairy, seems to have no significant trade barriers to foods derived from biotechnology. GT alfalfa has been approved for food and feed

and Mexico imports and consumes regularly GE corn, soybeans and cotton from the United States (FAS, 2008b). Mexico's existing labeling requirements for GMOs have not been implemented, according to Gruère G. P. (2006).

In the case of Canada, another important market for alfalfa downstream products from the United States, GT alfalfa has also been approved and there is no mandatory labeling for GE products (Gruère G. P., 2006).

### *2.2.2 Beyond Standards in Main Export Markets*

As in the case of Europe, mandatory labeling requirements for food in Japan have resulted in an incentive for producers to substitute non-GE ingredients for GE ingredients (Gruère G. P. and Rao S. R., 2007). Because of the higher threshold of GE content and exemptions of highly processed foods, there are still many products with GE ingredients that are sold in Japan without GE labeling, such as cheese, soya sauce and soy oil (Gruère G. P. and Rao S. R., 2007). Corn used for feed is typically GE corn, since meat fed with GE corn does not need to be labeled. Corn used for food consumption and soybeans used for Tofu, on the other hand, are typically GE free (Gruere G. P., 2006).

Because alfalfa hay is predominantly used as feed, the impacts of deregulation associated with the export market in Japan may be similar to those of soybean and corn. Japanese regulations do not seem to have had a significant impact on these crops and labeling is not required for products from GE fed animals, at least not for meat (Gruere, 2006).

However, for retail products where labeling is not required, there may still be a share of consumers that would prefer not to consume products with GM ingredients. Several consumer surveys suggest Japanese consumers would prefer not to consume foods with GE ingredients and would be willing to pay an extra amount for GE-free products (Chern et al., 2002; Bertolini et al., 2003). In these cases, it is up to producers to decide whether using GE ingredients – or GE feed in animal products – poses a risk to businesses.

There is evidence that businesses have often chosen to protect themselves against market risks associated with commercializing GE products, in face of consumer negative perceptions, even in the absence of labeling, at least in countries other than the United States. A USDA (2005) document notes how business associations have sometimes adopted lower required levels of unintended presence for acceptance of products than those required by legislation (United Kingdom). The same document notes that some insurance companies have added exclusions to insurance contracts to protect themselves from potential losses triggered by the presence of GE material.

There is some indication that Japanese alfalfa importers are concerned with importing GE alfalfa. Putnam (2005) states that foreign importers have asked for GE-free alfalfa and that this has lead U.S. exporters to require signed contracts from producers asserting the GE-free status of alfalfa sold to them. Similar anecdotal evidence is provided by Woodward (2004) and recognized in NAFA (2008b).

The attitude of businesses in the absence of required labeling in retail products can be explained by the perception of market risks associated with GE products, given consumer negative perceptions. The extent to which this attitude of businesses changes with time may depend on consumer information as well as on perceived and real liabilities in cases of losses due to the presence of GE material.

In the case of South Korea, Non-Government Organizations (NGOs) have increasingly pressured for expansion of labeling requirements to products using GE ingredients, independently of whether these can or cannot be detected in the final product (USDA FAS, 2008a). USDA FAS (2008a) notes that labeling of feed does not seem to have an impact in the market because most feed is GE, but that an expansion of food labeling requirements to include use of GE ingredients even when not detectable could turn South Korea into a non-GE market. As in the case of Japan, there is evidence of consumer negative views of GE products (Cho, Undated; USDA FAS, 2008a). South Korean businesses, however, have been opposing expansion of GE labeling given the potential increase in their costs from buying non-GE products.

### *2.2.3 U.S. Alfalfa Supply for Export Markets*

Something between 1.1% and 1.5% of U.S. alfalfa hay production was exported in 2007 (in metric tons, calculated comparing USDA FAS export data with production data as reported by USDA ERS, 2007). An exact number is not easy to achieve because exports are reported in hay, meal and pellets and weights must be compared to production alfalfa hay production. In 2007, exports of alfalfa seed represented approximately 54% of the quantity produced (in metric tons, calculated comparing USDA FAS export data with 2007 Census of Agriculture data).

We found no detailed information on the origin of alfalfa for exports within the United States. Various documents suggest a concentration of alfalfa hay and seed for exports in Western states. Woodward (2004) suggests 99% of hay exports come from Western states. Putnam (2005) suggests about 4.5% of alfalfa from six Western states (California, Washington, Oregon, Idaho, Nevada, Utah) is exported. Woodward (2004) notes some 20% of Washington alfalfa may be exported reaching 35%-50% in the Columbia Basin where the counties of Grant, Adams, Benton and Franklin produce almost 70% of the state's alfalfa hay. Putnam (2005) also suggests California's Imperial Valley production is highly aimed at export markets. Mueller (2005) estimates that about 80 percent of California alfalfa seed production goes for export. In all of these export-heavy regions, growers do not necessarily export their entire crop but possibly only a few cuttings (Putnam, 2005). This means that export markets may have a greater influence on production decisions than their share of the market.

### *2.2.4 Discussion*

The main U.S. client for alfalfa seed, Saudi Arabia, would currently not purchase GT alfalfa seeds. Whether Saudi Arabia would continue purchasing non-GT alfalfa seeds from the United States would likely depend on the extent to which non-GT alfalfa seed producers are able to avoid unintended presence of GT alfalfa traits.

United States sales of alfalfa for forage to Japan may decrease with GT alfalfa deregulation. There is evidence of precautionary resistance from Japanese importers for GT alfalfa and the United States has already been losing market share to competitors (Australia). Exporters may have to show that any unintended presence of GT traits would fall well below Japan's one percent threshold level for presence of GM feed.

Beyond the above, there is much uncertainty surrounding the future of trade of GM products. In our Technical Report *Downstream Effects to Organic Production and Marketing of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix T), we presented evidence that there is little information in Europe, Japan, United States, as well as in other countries, regarding GE products. To the extent that familiarity is related to acceptance (or rejection) of GE products, there is space for consumer receptivity to change or consolidate over time. Many countries do not have or must still implement their own regulatory systems for GE products (Gruère and Rao, 2007) and the analysis above is focused solely on U.S. current trading partners. Other potential future clients are not considered, although by far the main world importers are Japan and South Korea in the case of alfalfa hay and Saudi Arabia (after the United States) in the case of alfalfa seeds.

## 2.3 Summary of Findings

U.S. exports of alfalfa hay and processed alfalfa are considerably concentrated in Japan, and U.S. exports of alfalfa seeds have increasingly gone to Saudi Arabia. Japan and South Korea are the world's largest importers of forage and Saudi Arabia is the largest importer of alfalfa seed, after the United States.

Saudi Arabia will not import GT alfalfa seeds. There is no evidence, however, that Saudi Arabia will not continue to import non-GT U.S. alfalfa seed as long as exporters are able to guarantee seed purity standards.

There is evidence that Japan may decrease its imports of non-GT alfalfa hay from the United States with GT alfalfa deregulation. This seems to be motivated mainly by businesses concerned with negative reactions from consumers, even in the absence of labeling requirements in downstream dairy and meat products.

## 3.0 Impacts on Imports

### 3.1 Trends

#### 3.1.1 Alfalfa Seed

Imports of alfalfa seed by the United States were, in 2007, approximately \$36.5 million. As with exports, alfalfa seed imports by the United States have been growing since 2002.

**Table R-9. U.S. Alfalfa Seed Imports, \$ millions**

| 1997 | 1998 | 1999 | 2000 | 2001 | 2002 | 2003 | 2004 | 2005 | 2006 | 2007 |
|------|------|------|------|------|------|------|------|------|------|------|
| 14.5 | 20.4 | 16.3 | 11.8 | 12.7 | 10.9 | 13.4 | 15.9 | 18.0 | 24.9 | 36.5 |

Source: USDA FAS (FASonline). Code 120921 of the US Harmonized Tariff System. Includes certified and uncertified seeds.

Re-exports (exports that are subsequently resold to foreign markets) are not particularly significant: about \$954,000 in 2007, \$419,000 in 2006 (FASonline).

Alfalfa seed imports are mostly from Canada and some are from Australia. About a third of alfalfa seed imports are non-certified seeds.

**Table R-10. U.S. Alfalfa Seed Imports by Main Suppliers, \$ millions**

|           | 2003   | 2004   | 2005   | 2006   | 2007   |
|-----------|--------|--------|--------|--------|--------|
| Canada    | 11,403 | 13,219 | 10,489 | 17,794 | 29,669 |
| Australia | 1,489  | 2,677  | 7,228  | 6,915  | 6,080  |
| Others*   | 531    | 46     | 252    | 227    | 739    |
| Total     | 13,423 | 15,941 | 17,968 | 24,936 | 36,489 |

Source: USDA FAS (FASonline). Code 120921 of the US Harmonized Tariff System. Includes certified and uncertified seeds.

\*Includes Argentina, Italy, and France, among others.

According to Revision 2 of the 2008 US Harmonized Tariff Schedule, alfalfa seed imports from Canada, Australia and several other countries are free from the 1.5 cents/ Kg normal import tariff.

#### 3.1.2 Alfalfa Hay and Processed Alfalfa

Imports of alfalfa hay were approximately \$7 million in 2007. In recent years alfalfa hay imports have increased steadily and 2007 imports were nearly three times those of 2003. The United States receives the vast majority of its alfalfa hay imports from Canada and most of the remaining imports from Mexico.

**Table R-11. U.S. Alfalfa Imports (Hay Bales), \$1,000**

|         | 2003  | 2004  | 2005  | 2006  | 2007  |
|---------|-------|-------|-------|-------|-------|
| Canada  | 1,873 | 2,366 | 2,376 | 3,471 | 5,493 |
| Mexico  | 20    | 57    | 5     | 75    | 1,298 |
| Others* | 454   | 11    | 49    | 68    | 8     |
| Total   | 2,348 | 2,435 | 2,430 | 3,613 | 6,800 |

Source: USDA FAS (FASonline). Code 1214900010 of the U.S. Harmonized Tariff System. \*Includes New Zealand and Argentina, among others.

Imports of processed alfalfa were approximately \$16 million in 2007. Processed alfalfa imports have also risen steadily in recent years and have almost doubled since 2003. Almost all of the U.S. processed alfalfa imports come from Canada.

**Table R-12. U.S. Processed Alfalfa Imports, \$1,000**

|         | 2003  | 2004  | 2005  | 2006   | 2007   |
|---------|-------|-------|-------|--------|--------|
| Canada  | 8,212 | 7,238 | 9,163 | 8,474  | 14,627 |
| Mexico  | 0     | 1,315 | 0     | 1,257  | 1,379  |
| Others* | 105   | 181   | 208   | 2401   | 396    |
| Total   | 8,317 | 8,735 | 9,373 | 12,131 | 16,403 |

Source: USDA FAS (FASonline). Code 121410 of the U.S. Harmonized Tariff System. \*Includes France and Hungary, among others.

## 3.2 Impacts of GT Alfalfa Deregulation

### 3.2.1 The Demand for Alfalfa Imports

In our Technical Report *Economic and Social Impacts to Conventional and Organic Farmers of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix S), we argued that deregulation of GT alfalfa will likely generate a downward pressure on prices of conventional alfalfa hay (both GT alfalfa and non-GT alfalfa). This would likely lead to increased domestic consumption of both alfalfa hay and alfalfa seed. This increase in consumption would be accompanied by market segmentation, where the consumption of non-GT alfalfa hay and seed would cede space to the consumption of GT alfalfa hay and seed.

If the United States loses export markets due to GT alfalfa deregulation (as we argued in section 2 may happen), this would generate additional domestic supply of conventional non-GT alfalfa hay and seed, likely further decreasing its price. If exported hay and seed is now channeled to domestic markets the result may be a decrease in demand for imports. The United States is highly competitive in forage and alfalfa seed, as revealed by its position as one of the largest net exporters (tables R-13 and R-14) and domestic production should be able to compete with imports.

**Table R-13. Largest Net Exporters of Forage, 2007, US\$**

|               | Exports     | Imports    | Net Exports |
|---------------|-------------|------------|-------------|
| United States | 622,144,650 | 48,386,339 | 573,758,311 |
| Australia     | 202,892,772 | 87,401     | 202,805,371 |
| Canada        | 185,121,059 | 5,359,957  | 179,761,102 |

Source: UN Comtrade, 2007. Code 1214 of the Harmonized System. Includes swedes, mangolds, fodder roots, hay, lucerne (alfalfa), clover, sainfoin, forage kale, lupines, vetches and similar forage products, whether or not in the form of pellets

**Table R-14. Largest Net Exporters of Alfalfa Seed Used for Sowing, 2007, US\$**

|               | Exports    | Imports    | Net Exports |
|---------------|------------|------------|-------------|
| Canada        | 40,107,509 | 3,700,730  | 36,406,779  |
| United States | 67,008,403 | 36,884,441 | 30,123,962  |
| Australia     | 25,399,677 | 22,430     | 25,377,247  |

Source: UN Comtrade, 2007. Code 120921 of the Harmonized System.

If, however, imported alfalfa hay and seed are qualitatively different from local produced hay and seed, imports may not be affected and may actually grow in some segments. One segment in

which imports could grow is that of non-GT alfalfa seed, if U.S. stewardship programs are seen as insufficient to guarantee seed purity levels. We have no reliable information on variety details of exports and imports of alfalfa hay and seed.

In our Technical Report *Downstream Effects to Organic Production and Marketing of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix T), we found no evidence that GT alfalfa deregulation will have a negative impact on main domestic downstream markets. We thus do not foresee impacts on imports in downstream markets.

### 3.2.2 The Supply of Alfalfa Imports

The main world providers (exporters) of alfalfa seed other than the United States (largest exporter) are Canada and Australia. These are also the main providers of alfalfa seed to the United States and Canada's exports are already heavily focused on the U.S. market (table R-15). Australia's exports are more diversified (table R-16)<sup>69</sup>.

**Table R-15. Canada Alfalfa Seed Exports, \$1,000**

|               | 2003   | 2004   | 2005   | 2006   | 2007   |
|---------------|--------|--------|--------|--------|--------|
| United States | 11,780 | 13,371 | 10,425 | 17,929 | 30,484 |
| Other         | 7,162  | 9,953  | 4,544  | 9,078  | 9,517  |
| Total         | 18,942 | 23,324 | 14,969 | 27,007 | 40,001 |

| Total         | 25,400 |

Source: UN Comtrade, 2007. Code 120921 of the Harmonized System.

In the case of forage, United States is again the World's largest provider followed by Australia and Canada. United States' main provider (Canada) exports considerably larger sums to Japan of forage in general (table R-17) and alfalfa meal and pellets in particular (table R-18) than to the United States

**Table R-17. Canada Forage Exports, \$1,000**

If GT alfalfa deregulation reduces U.S. exports to Japan, it is likely that Canada and Australia would try to fulfill the existing gap left by the United States. This would possibly reduce the supply of foreign non-GT alfalfa available for import to the U.S. This would impact U.S. trade only to the extent that particular varieties are imported rather than domestically produced, assuming the domestic market would already be facing an excess supply of non-GT alfalfa hay and seed.

### 3.3 Summary of Findings

U.S. imports of alfalfa hay and seed come mostly from Canada. To the extent that GT alfalfa deregulation reduces foreign demand for U.S. exports, alfalfa hay and seed production previously destined to foreign markets may be channeled to the domestic market. As the domestic market for non-GT alfalfa hay and seed is expected to decrease with GT alfalfa deregulation, U.S. production is likely to substitute imports.

## Appendix R-2. Literature Search

### 1.0 Literature Search Strategy

Most U.S. trade data was obtained from USDA's Foreign Agriculture Service. For other countries we made use of foreign government data sources or the United Nations' Commodity Trade Statistics Database (Comtrade).

Much of the literature researched was on the market receptivity to GMOs. As in our Technical Report *Downstream Effects to Organic Production and Marketing of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix T), the search started with general internet searches and then snowballed from references found in various papers.

We found particularly useful reports elaborated by the Global Agriculture Information Network of USDA's Foreign Agriculture Service.

## Appendix R-3. County Level Analysis

In the Technical Reports *Changes in the Economics of Alfalfa Farming with Deregulation of Glyphosate-Tolerant Alfalfa* (appendix K) and *Economic and Social Impacts to Conventional and Organic Farmers of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix S) we included appendices analyzing county level implications of the information raised in each of those reports. The analysis done was limited to the scope of the reports they were a part of. In the present appendix R-3, we make a few considerations on the county level analysis done in those two reports, given the information on foreign trade that we have now gathered.

In the first of the two reports mentioned above, a ranking of counties that would most likely benefit from deregulation of GT alfalfa was done, based on the likelihood that a randomly picked acre from that county harvested forage alfalfa treated with herbicide. This ranking ignored any considerations regarding sensibilities in the end markets. In the present report we observed that foreign markets are often sensitive to the presence of GE material in food and feed. Counties producing for such markets may find it in their best interest to not plant GT alfalfa, even if ranked highly in the first of the above Technical Reports.

Unfortunately, there is no information available on alfalfa hay exports by county of origin. However, a few considerations can be made regarding our previous ranking. First, the highest ranked county in the Technical Report (appendix K) was Brown County, Wisconsin, and the hay produced in that county is unlikely for export and may adopt GT alfalfa. However, the second ranked county, Imperial County, California is unlikely to adopt GT alfalfa (telephone and email exchanges with two alfalfa experts, Dan Putnam and Shannon Mueller, between July 24 and August 06). Among the various reasons, the production of seed for foreign markets may be one of them. Second, as Imperial County, other counties may be particularly interested in export markets and thus not be willing to adopt GT alfalfa even if they were previously ranked as likely to benefit. Third, a few counties have already banned GM crops. Marin, Mendocino, Santa Cruz and Trinity have all passed legislation banning production of GE crops. Of these counties, only Mendocino had some alfalfa production in the 2007 Agricultural Census and was ranked among the 220 counties least to benefit from GT alfalfa deregulation (from 2305 counties with alfalfa production) in the first Technical Report (appendix K) mentioned above.

In the second of the two reports mentioned above, we ranked counties according to their revealed economic interest in producing alfalfa seed, while relatively little in producing alfalfa for forage with herbicide. Imperial County appears in first place, potentially explaining its resistance to GT alfalfa deregulation by the importance of alfalfa seed in that county.

Additional considerations would be possible if data were available for the source by county and country of destiny of U.S. alfalfa seed and forage exports.

**Appendix S: Economic and Social Impacts to  
Conventional and Organic Farmers of  
Deregulation of Glyphosate-Tolerant  
Alfalfa**

# **Economic and Social Impacts to Conventional and Organic Farmers of Deregulation of Glyphosate-Tolerant Alfalfa**

## **Executive Summary**

This report analyses the potential social and economic impacts to conventional and organic farmers regarding the deregulation of glyphosate-tolerant (GT) alfalfa, due to changes in demand and supply in the domestic market.

As farmers switch to producing GT alfalfa and as the demand for non-GT alfalfa falls, the impact of GT alfalfa deregulation on non-GT conventional alfalfa farmers will likely be a reduction in the market for non-GT alfalfa. The resulting final price for non-GT alfalfa is not clear, but it will likely be lower than it otherwise would be, decreased by the higher returns of its substitute: GT alfalfa. During a period of adjustment to the new market segmentation between GT alfalfa and non-GT alfalfa, prices will tend to fall if demand shifts faster to GT alfalfa than farmers, or will tend to rise if farmers shift faster than demand.

The impact of GT alfalfa deregulation on organic alfalfa farmers depends on whether there is a share of the domestic organic alfalfa market that is sensitive to products with genetic engineering (GE). With no GE sensitivity of demand, the only possible impact on organic markets is the downward shift in demand that follows the reduction in prices of conventional alfalfa, leading to a reduction in prices and quantities sold domestically of organic alfalfa. In the case of GE sensitivity of demand in organic alfalfa markets, the result of GT alfalfa deregulation depends on the extent of this GE sensitivity: the larger the GE sensitive market is, the more likely quantities sold will fall, although with unclear effect on prices. The larger the non-GE sensitive market is, the more likely prices will fall but with unclear effect on quantities.

GT alfalfa adoption by farmers, presence of GT alfalfa in non-GT alfalfa fields, and the demand response to GT alfalfa deregulation will have several distributional and social impacts: the loss and gain of businesses, changes in market structure, distribution of the costs of loss of production and avoidance in GE sensitive markets, and potential negative impacts on the preferred environment of organic farmers (one free of GE organisms).

## 1.0 Introduction

### 1.1 Scope of Report

This report analyzes the potential social and economic impacts to conventional and organic farmers due to the deregulation of glyphosate-tolerant (GT) alfalfa. We expand on our Technical Report *Changes in the Economics of Alfalfa Farming with Deregulation of Glyphosate-Tolerant Alfalfa* (appendix K), moving beyond changes in costs and yields within alfalfa farms, to discuss aggregate impacts on the supply of conventional and organic alfalfa.

We also incorporate domestic demand to our analysis leaving, however, foreign demand for our Technical Report *Impacts to United States Trade of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix R).

Below we explain the methodology – assumptions, scenarios and limitations – upon which this analysis is based.

### 1.2 Methodology

Analysis of the potential impact of deregulation of GT alfalfa on US organic farming was divided in its impact on the demand for organic alfalfa and its impacts on the supply of organic alfalfa in the U.S. market. When analyzing the potential impact on demand of organic alfalfa, we ignore any impacts on supply. Similarly, when analyzing the potential impact on the supply of the organic alfalfa, we ignore any impacts on demand. We then proceed to look at both demand and supply jointly.

This procedure is meant to facilitate the analysis and to improve our understanding of the sources and mechanisms of the impact of GT alfalfa deregulation. It is a conventional approach in economics, and under this approach prices and quantities are determined jointly by supply and demand. This means that in analyzing shifts in demand and supply, we will not consider how demand and supply change *in response to prices* – because prices are determined by demand and supply themselves. Rather, we look at how demand and supply change in response to other factors and draw conclusions about the resulting changes in prices and quantities. It is important to keep this in mind to understand the analysis done in this report.

We will often refer to impacts on supply and demand as “shifts,” that move the “demand curve” or the “supply curve” upwards or downwards. This language is best understood in reference to the conventional graph of supply and demand below. In this graph, an upwards shift in demand is illustrated.

**Figure S-1: Upward shift in demand**

The economic analysis of shifts in demand and supply in the alfalfa market is complex because the market is segmented in various ways: domestic and international, conventional and organic, high quality and low quality, and for the purposes of this study: markets sensitive to genetically engineered (GE) products and non-GE sensitive markets. To the extent that alfalfa of various qualities and destined to various markets are substitutes, shifts in supply in one market segment may result in shifts in both supply and demand in another. We often simplify our analysis and try to be explicit about the simplifications made.

In this report we generally do not refer to forage in general but rather hay because there is more data available on hay than other types of forage (haylage). This has no significant impact on our analysis and we do make reference to haylage when deemed appropriate. When no distinction between seed and hay is relevant, we often refer simply to alfalfa, alfalfa stands or alfalfa fields.

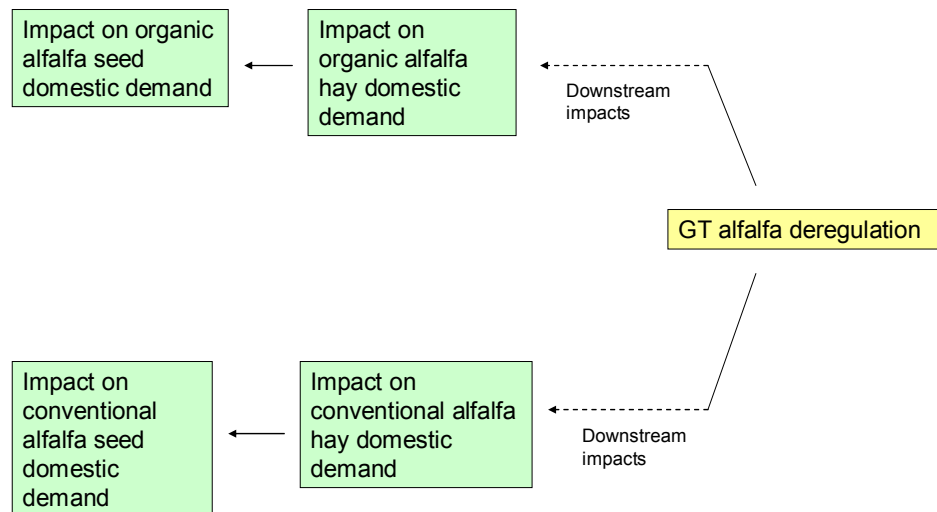

Section 2 of this report analyzes potential shifts in the demand of conventional and organic alfalfa induced by the deregulation of GT alfalfa. Section 3 does the same for the supply of conventional and organic alfalfa. In both sections we start by looking at current data and expected trends and then turn to discuss potential impacts of deregulation. In section 4 we combine our analysis of each side of the market and discuss potential impact scenarios

No quantitative estimates of the impacts of GT alfalfa deregulation are offered in this report. We feel there is not sufficient information for such estimates. However, we describe in section 4 what lacking evidence would allow such estimates for specific impact scenarios.

In appendix S-2 of this technical report we describe our bibliographic and data search. Appendix S-3 of this technical report is a county level analysis that expands on the similar analysis done in our Technical Report *Changes in the Economics of Alfalfa Farming with Deregulation of Glyphosate-Tolerant Alfalfa* (appendix K). It ranks alfalfa seed producing counties by acreage and the likelihood of not finding alfalfa hay with herbicides, where the latter variable is taken as an indicator of reduced losses in not producing GT alfalfa hay.

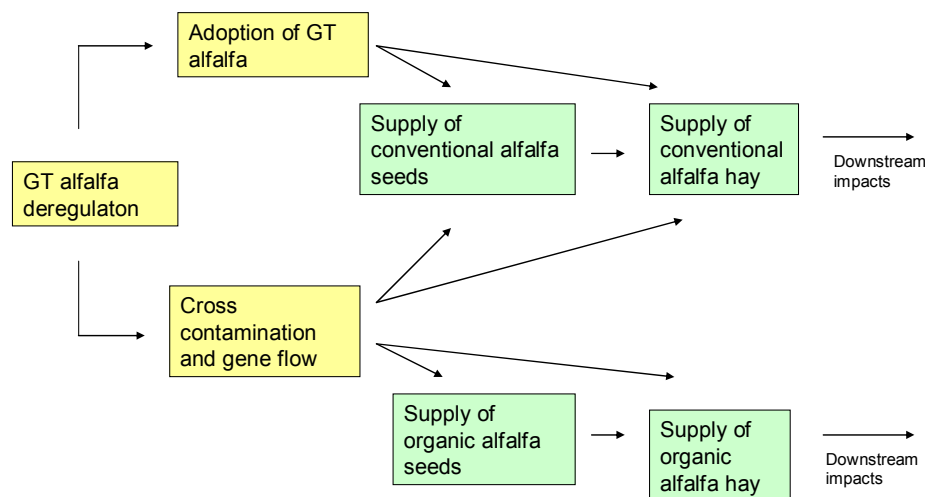

### 1.2.1 Assumptions

GT alfalfa deregulation is assumed to potentially affect organic and conventional alfalfa demand to the extent that it affects dairy, livestock, pet care and human domestic demand through perception of the presence of GT alfalfa material in these products. Changes in demand for alfalfa hay and alfalfa fields for human consumption reflect on changes in demand for alfalfa seed. The figure below illustrates the cause-effect links to be analyzed.

**Figure S-2: Deregulation impact on demand**

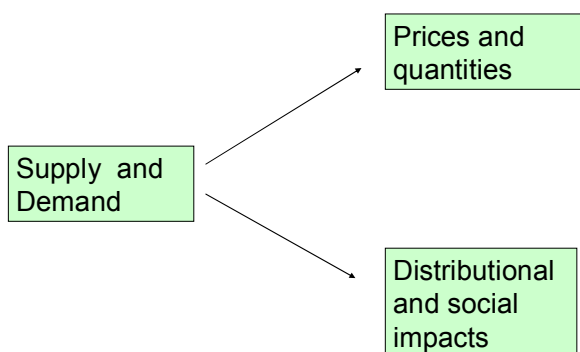

On the supply side, GT alfalfa deregulation will generate two sources of impacts. The first is the adoption of GT alfalfa by conventional farmers. This adoption will impact supply to the extent that GT alfalfa has its own quality and cost properties. The second is the possible comingling of GT alfalfa seeds among non-GT alfalfa seeds and gene flow from GT alfalfa fields to non-GT alfalfa fields. The figure below illustrates the cause-effect links analyzed.

**Figure S-3: Deregulation impact on supply**

Comingling and gene flow may reduce the availability of seeds accepted as organic or free of GE material and may increase the costs of farmers in avoiding comingling and gene flow and in screening for GE material.

The interaction of the impacts on supply and demand will result in impacts on prices and quantities sold, and will impact differently on various segments of farmers. Some farmers may lose business with comingling and gene flow. Others – possibly depending on location – may gain, as may GT alfalfa farmers. Who gains or loses may have impacts on the market structure. It may also have an impact on perceptions of freedom of choice and on perceptions of justice associated with the distribution of the burden (among consumers of organic products as opposed to consumers of GE products, for example). Deregulation may also have social impacts, particularly on organic farmers and consumers.

**Figure S-6: Supply and demand**

### *1.2.2 Data and Information Sources*

Most of our data was obtained from USDA sources, under the assumption that these are the best quality agriculture statistics available. This data was complemented with information obtained from academic journal articles, or from Cooperative Extension services, peer-reviewed whenever possible, under the assumption that these documents are subject to standards that should help reduce if not eliminate any intentional bias.

Our primary source of data for acreage and production was USDA's National Agriculture Statistics Service (NASS). NASS collects data annually through a series of surveys based on representative samples, including area surveys and yield surveys. We also made use of data published by USDA's Economic Research Service, typically also compiled from NASS surveys. In cases where recent survey data was not available, we used the latest Census of Agriculture (2007), comparing with the previous Census of Agriculture (2002 and or 1997) when this was considered informative.

In the case of organic agriculture there is less availability of data. USDA has been collecting data on acreage. As yields vary substantially, production estimates are tentative.

## 2.0 Impacts on Demand

### 2.1 Alfalfa Demand

An analysis of demand for alfalfa should distinguish between demand for alfalfa hay, demand for alfalfa seeds, and demand for alfalfa for human consumption, each with its own particular market and market characteristics. Demand for alfalfa hay (as well as products such as haylage, meal, and pellets processed from hay) derives mostly from the dairy industry, but also from the meat producing industry and from other livestock and pet care. Alfalfa is also available for human consumption in the form of alfalfa sprouts and alfalfa leaves, which can be dehydrated and used as a dietary supplement in tablets, powders, or tea.

In addition, the honey industry utilizes alfalfa fields for honey production. As noted in the Technical Report *Downstream Effects to Organic Production and Marketing of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix T) addressing downstream effects of GT alfalfa deregulation, the honey industry utilizes alfalfa fields for honey production. Alfalfa produces a large amount of nectar, which is attractive to some species of bees, and from which honeybees produce excellent crops of high quality honey (McGregor 1976). The actual market “demand” for alfalfa hay fields by beekeepers appears to be small to non-existent. Alfalfa seed producers contract with bee keepers for pollination services, with honey production being sometimes a co-benefit retained by the bee keeper. Pollination services are an important interstate business. Brady-Myerov (2006) reported that 80 percent of the approximately 2.3 million commercial bee colonies that existed in the United States in 2006 needed to be trucked to California almond orchards just to meet pollination service demand. Brady-Myerov (2006) noted that the going rate for pollination services in 2006 was approximately \$125 to \$150 per hive for six weeks of orchard placement.

In contrast, when alfalfa is cut for hay just at the start of the flowering stage, as is normally practiced, beekeepers get little or no alfalfa honey (McGregor 1976). Beekeepers may keep hives near alfalfa hay fields to access any blossoms prior to cutting, but we found no evidence that beekeepers engage in a commercial market exchange to purchase nectar harvesting services from hay farmers.

Demand for alfalfa seeds is derived primarily from the demand for establishing new stands of alfalfa hay, as well as much smaller demand derived from alfalfa sprout producers and from other processed alfalfa products for human consumption.

GT alfalfa deregulation will affect organic and conventional alfalfa demand to the extent that it affects dairy, livestock, pet care and various forms of human consumption domestically. These impacts are mediated by consumer concerns about consumption of GE foods, or use of GE animal feeds. The extent to which GT alfalfa deregulation will potentially affect conventional and organic alfalfa demand is also influenced by the price, availability, and comparability of substitutes.

### 2.1.1 Domestic Demand for Alfalfa for Forage

There seems to be no complete and systematic data on alfalfa for forage consumption in the US (Klonsky et al, 2007). However, an approximate aggregate value of the demand for alfalfa hay can be obtained through production and trade statistics<sup>70</sup>.

USDA's National Agricultural Statistics Service (NASS) estimates the value of alfalfa hay production in the US to have been approximately US \$9 billion in 2007. This number was obtained by multiplying average prices with volumes produced and does not correspond to actual sales. Sales must have been much less. According to Klonsky et al (2007), most of the alfalfa hay produced in the United States is consumed on farm.

If we discount from these US \$9 billion the US \$171 million in alfalfa hay exports and add the US \$7 million in imports, we have a domestic market for alfalfa hay of approximately US \$8.8 billion in 2007. The same reasoning would lead to a domestic market of US \$7.5 billion in 2006 and US \$7.2 billion in 2005.

**Table S-1. Domestic Alfalfa Hay Market (US \$1,000)**

|             | <b>2007</b> | <b>2006</b> | <b>2005</b> |
|-------------|-------------|-------------|-------------|
| Production  | 8,972,483   | 7,668,870   | 7,342,000   |
| Exports     | 170,925     | 165,192     | 165,087     |
| Imports     | 6,800       | 3,613       | 2,430       |
| Consumption | 8,808,358   | 7,507,291   | 7,179,343   |

Sources: Production data from USDA NASS (2008a); Trade data from USDA Foreign Agricultural Service (FAS); Consumption calculated as production – exports + imports, and assuming change in alfalfa inventories is zero. \* Imports reported of Alfalfa Bales, as opposed to Alfalfa Hay

We found no data on the national distribution of the consumption of alfalfa hay among its various uses. Putnam (2005) states that the three main domestic markets for alfalfa are dairy farms, beef farms and horse farms, with minor uses of alfalfa hay “for small ruminants (sheep, goats), alfalfa meal for processed feeds, and alfalfa pellets for pets and rabbits.” Of these, dairy farms are “by far” the main consumer. Klonsky et al. (2007) estimate dairy farms to absorb between 75%-85% of alfalfa hay in California, with another 10%-15% destined to horses and 5%-10% to beef.

One indication of the role of dairy farms on alfalfa hay consumption can be found by multiplying the number of dairy cows in the United States by an estimate of alfalfa hay intake. If we follow Hoyt (2001) and estimate an intake of 15 pounds of alfalfa hay per day per dairy cow, another 7 pounds a day for milk replacement heifers and another 3 pounds a day for dairy heifers under 500 pounds, and assume the proportion between milk cows, milk replacement heifers and heifers under 500 pounds is roughly 4:2:1, we have an estimated consumption of alfalfa hay for dairy of approximately 177 million pounds per day or 32.8 million tons a year:

9.2 million milk cows in 2007 (USDA ERS, 2008) x 15 lb = 138 million lb

4.6 million replacement heifers x 7 lb = 32.2 million lb

3.2 million heifers under 500 pounds x 3 lb = 9.6 million lb.

<sup>70</sup> Assuming the accumulation of stored alfalfa hay over time is zero.

Total: 179.8 million lb/day or 65,627 million lb/year or 32.8 million tons (short)/year  
This corresponds to roughly 46% of the domestic market estimated at 71.8 million tons in 2007 (72.6 million tons produced, minus exports, plus imports)<sup>71</sup>. These data suggest that the share of alfalfa hay demand deriving from non-dairy sources (beef production, horse care, and secondary processing into meal and pellets) is larger nation-wide than in California, the top dairy-producing state in the US (California Department of Food and Agriculture 2005).

The quality of alfalfa hay is guided by the low presence of weeds, by relatively low content of fiber and high content of protein, and other factors such as color and presence of mold (Klonsky et al, 2007). Categories are classified in different ways. USDA's Agricultural Marketing Service uses the grades of supreme, premium, good, fair and utility to regularly report average prices in various states. They describe each grade as follows:

- Supreme: Very early maturity, pre bloom, soft fine stemmed, extra leafy. Factors indicative of very high nutritive content. Hay is excellent color and free of damage
- Premium: Early maturity, i.e., pre-bloom in legumes and pre head in grass hays, extra leafy and fine stemmed-factors indicative of a high nutritive content. Hay is green and free of damage.
- Good: Early to average maturity, i.e., early to mid-bloom in legumes and early head in grass hays, leafy, fine to medium stemmed, free of damage other than slight discoloration.
- Fair: Late maturity, i.e., mid to late-bloom in legumes, head-in grass hays, moderate or below leaf content, and generally coarse stemmed. Hay may show light damage.
- Utility: Hay in very late maturity, such as mature seed pods in legumes or mature head in grass hays, coarse stemmed. This category could include hay discounted due to excessive damage and heavy weed content or mold. Defects will be identified in market reports when using this category. (USDA AMS, 2008)

Other sources note that alfalfa hay quality grades differ to some degree from state to state (McWilliams et al. (2005), or speak of high quality alfalfa as being “dairy-quality” (Klonsky et al, 2007). According to Klonsky et al (2007), there is no clear cut classification for alfalfa hay quality.

*Hay quality guidelines are published by USDA Hay Market News, but quality factors are generally loosely decided by industry habit and practice, and can be freely modified by individual buyers and sellers, depending on their needs and the realities of the market.*

Dairy cattle and horses both tend to have high forage quality requirements (Van Deynze et al. 2004). Most weeds are lower in forage quality or palatability than alfalfa, and forage with high weed content can adversely affect milk production as well as animal growth and health (Van Deynze et al. 2004). Forage quality requirements for sheep and goats are not as rigorous. Beef producers in particular, facing relatively low margins, are apparently a market for lower quality (and cheaper) alfalfa (Klonsky et al, 2007).

---

<sup>71</sup> Production data from USDA ERS, 2007. Trade data from USDA FAS (online searchable database). Trade data is available in metric tons, transformed to short tons by multiplying by 1.10231.

Some states provide data on prices of different hay qualities. Table S-2 below shows some of the price differences expected of different hay qualities in some areas of California. The table also illustrates differences in prices depending upon location. As shown, prices can vary by more than 50 percent depending on quality and location. Distinctive regional alfalfa markets likely reflect the importance of transportation costs in limiting the trucking of relatively high volume, low value alfalfa hay across longer distances.

**Table S-2. Price Differences of Hay Qualities, 10-Year Average, 1997-2006**

| Region                           | Hay Quality Category |         |        |        |
|----------------------------------|----------------------|---------|--------|--------|
|                                  | Supreme              | Premium | Good   | Fair   |
| <b>Southern California</b>       |                      |         |        |        |
| <i>Imperial Valley</i>           | 121                  | 115.24  | 100.29 | 86.35  |

### 2.1.2 Domestic Demand for Alfalfa Seed

The demand for alfalfa seed derives from the demand for establishing new stands of alfalfa hay, and to a much lesser extent from the demand for alfalfa products destined for human consumption. As in the case of alfalfa hay, the domestic alfalfa seed market can be estimated based on available data for production, exports and imports. The last year for which complete data is available is 2007, the year of the last Census of Agriculture.

**Table S-3. Domestic Alfalfa Seed Market (US \$1,000)**

|             | 2007   | 2002   | 1997    |
|-------------|--------|--------|---------|
| Production  | 93,173 | 66,724 | 104,492 |
| Exports     | 66,094 | 25,963 | 50,372  |
| Imports     | 36,363 | 10,864 | 14,521  |
| Consumption | 63,442 | 51,625 | 68,641  |

Sources: Production data from USDA Census of Agriculture (2007, 2002, 1997); Trade data from USDA Foreign Agricultural Service (FAS); Consumption calculated as production – exports + imports, and assuming change in alfalfa inventories is zero.

Table S-3 suggests the domestic demand for alfalfa seeds in 2007 was approximately US\$ 63 million, up from US\$ 52 million in 1997. Imports represented some 64% of domestic demand, although it is possible that some of these imports were re-exported.

### *2.1.3 Domestic Demand for Alfalfa for Human Consumption*

Some alfalfa seed is used to produce sprouts for human consumption. Seed for sprouting is produced throughout the world, but the major suppliers are in the US, Canada, and Australia. Approximately 80 million pounds of alfalfa seed are produced each year in the United States. 85% of that is produced in five western states – California, Idaho, Oregon, Washington, and Nevada. The balance is from Arizona, Utah, Montana, Wyoming, and other states. The primary market for that seed is planting stock to produce forages to support the livestock industry in the United States and throughout the world. Only a small fraction of the seed produced is used for sprouting (Mueller, Undated).

There does not appear to be any publicly available sales data for alfalfa sprouts. In testimony given in a public meeting convened by the United States Department of Health and Human Services' Food and Drug Administration (1998), sprout industry expert Dr. Earl Hauserman noted that as of 1998 there were about 350 sprouters in the US. He noted that green sprouts (alfalfa, broccoli, clover, mustard, onion, radish, sunflower, and other sprouts) amount to about \$80 million a year in sales. Hauserman also stated that alfalfa sprouts account for about 75-80% of the green sprout market, or \$60-\$64 million in annual sales. Hauserman stated that U.S. sprouters utilize approximately 125,000 to 150,000 pounds of alfalfa seed a month to produce about five to six million four ounce packages a month. On an annualized basis, Hauserman's testimony would imply that 1998 alfalfa sprouters purchased 1.5-1.8 million alfalfa seeds, and produced 15-18 million pounds of alfalfa sprouts. Hauserman estimated that between five and 10 percent of US residents consume sprouts of various kinds.

Dehydrated alfalfa leaf is commercially available as a dietary supplement in several forms, such as tablets, powders and tea. Alfalfa is also believed by some to be useful as an herbal or homeopathic medicine (Foster and Johnson 2006). Once again there does not appear to be any publicly available sales data for alfalfa produced for dietary supplements, herbal remedies, or homeopathic medicines. Nelson (2008) reports an estimate that the total US alfalfa supplement market could be satisfied with 10 tons of alfalfa hay production, which could be produced on 1-2 acres.

### *2.1.4 Domestic Demand for Organic Alfalfa for Forage*

As in the case of non-organic alfalfa for forage, organic alfalfa also faces a derived demand, mainly from the demand for organic dairy and beef (Butler 2002). The higher price of organic hay (described later in this section) will generally deter conventional livestock producers from using organic alfalfa when it is not necessary to do so.

To be sold as organic in the United States, alfalfa hay must meet standards established by the Organic Foods Production Act of 1990 and the National Organic Program (NOP) that became effective in 2001. According to these standards, to be sold as organic, dairy and meat products must come from dairy cows and livestock fed 100% with organic feed, with the exception of vitamin and mineral supplements (USDA NOP 2008). NOP standards also state that dairy animals must be managed organically for at least 12 months in order for milk or dairy products to be sold, labeled or represented as organic. Dairy producers may use land that is transitioning during its third year of transition to organic certification to provide crops and forage for dairy

animals during this 12-month period prior to the sale of dairy products as organic (USDA NOP 2008).

Information on organic alfalfa hay acreage is available from USDA Economic Research Service for 2005 (we cover this in section 3 on alfalfa supply). However, we found no publicly available information on trade in organic alfalfa, making estimates of domestic demand impossible. If domestic demand for organic alfalfa follows the same trend of organic alfalfa hay production, it is a growing demand. As shown in section 3, organic alfalfa hay represented in 2005 0.92% of total alfalfa hay harvested acreage, up from 0.51% in 2000.

There is likely a GE sensitive segment of the market for most organic products. The first version of the National Organic Program published by the USDA in 1997 did not exclude GE organisms. After the over 270,000 comments received to this first version, this was one of the main aspects changed (Hubbard, 2006), even though there are not set tolerance levels for the presence of unintended genetically engineered material (the organic certification standard focuses on the process rather than the product). We found no information on the possible size of the GE sensitive segment of the market for organic products in the United States. We will argue further below, however, that opposition to genetic engineering within the organic market may not translate to reduced demand in the case of alfalfa hay.

Prices and quality requirements are significantly different between organic and non-organic alfalfa hay. In its *Organic Alfalfa Hay* report, the University of California found that prices for organic alfalfa hay will vary depending on season, the market, and quality, but will be approximately 20 percent greater than prices for conventional hay (Long et al., 2007).

Table S-4 shows how prices differ between organic and conventional alfalfa hay in Escalon, Modesto, and Turlock counties in California in 2007. The average premium reported in this particular data set is slightly greater than 20 percent.

**Table S-4. Prices for Organic and Conventional Alfalfa Hay; Escalon, Modesto, Turlock, California 2007**

### *2.1.5 Domestic Demand for Organic Alfalfa Seeds*

Demand for organic alfalfa seeds derives from the demand for organic alfalfa hay, as the NOP requires the use of organic seeds to establish organic alfalfa stands (CFR Title 7, §205.204). However, an exception is made to the requirement of using organic seeds in cases where these are not available<sup>72</sup>. In these cases, untreated conventional seeds or seeds treated with substances included in the National List of synthetic substances allowed for use in organic crop production are typically allowed.

We were not able to estimate the demand for organic alfalfa seed, due to the lack of data on production of organic alfalfa seed as well on organic seed trade. It is possible that the fact that non-organic seeds are allowed for the production of organic alfalfa hay has reduced the demand of organic alfalfa seed and incentives for production.

However, some demand is likely to exist and it may be currently supplied by either domestic or imported production (imported seeds were in 2002 approximately 21% of domestic consumption, in 2007, imported seed were 64% of domestic consumption). The Organic Materials Review Institute (OMRI), a nonprofit managed by the organic industry that self-regulates allowed substances in organic production, reports three suppliers of organic alfalfa seed for forage in its seed database (<http://seeds.omri.org/index.php?dosearch=1&terms=alfalfa&submit=Go>). Some of this seed is imported from Canada.

Baker (2008) notes that the main reason reported by organic certifiers to accept farmers claims that organic seeds are not available is the claim that available seeds are not “equivalent” to non-organic available seeds in their desired qualities. When asked what crop was most claimed to not have available organic seeds, certifiers identified alfalfa. This may be an indication of an unfulfilled demand that, given the growth rates in organic alfalfa seed production, is likely to stimulate the development of “equivalent” organic varieties that may now not be available. The supply to satisfy this demand may come from domestic or foreign sources.

### *2.1.6 Domestic Demand for Organic Alfalfa for Human Consumption*

As noted in section 2.1.3 above, some alfalfa seed is used to produce sprouts for human consumption. Seed for sprouting is produced throughout the world, but the major suppliers are in the US, Canada, and Australia. The primary market for alfalfa seed, however, is planting stock to produce forages to support the livestock industry in the US and throughout the world. Only a small fraction of the seed produced is used for sprouting (Mueller, undated). There does not appear to be any publicly available sales data for organic alfalfa sprouts. Using data drawn from the US Department of Health and Human Services’ Food and Drug Administration (1998), it is estimated in section 3.1.3 that 1998 alfalfa sprouters purchased 1.5-1.8 million alfalfa seeds, and produced 15-18 million pounds of alfalfa sprouts. Presumably organic sprout production in 1998 was some fraction of total sprout production.

As noted in section 2.1.3 above, dehydrated alfalfa leaf is commercially available as a dietary supplement in several forms, such as tablets, powders and tea. Alfalfa is also believed by some

---

<sup>72</sup> This exception is not made for production of organic edible sprouts.

to be useful as an herbal or homeopathic medicine (Foster and Johnson 2006). Once again there does not appear to be any publicly available sales data for alfalfa produced for dietary supplements, herbal remedies, or homeopathic medicines. Nelson (2008) reports an estimate that the total US alfalfa supplement market could be satisfied with 10 tons of alfalfa hay production, which could be produced on 1-2 acres.

## 2.2 Impact of GT Alfalfa Deregulation

### 2.2.1 *Shifts in Demand*

The quantity of alfalfa hay demanded depends on its price and quality. Quality is mostly influenced by the presence of weeds. The impact of GT alfalfa deregulation on price (and quantities) will be the result of its impact on the remaining determinants of demand and supply. We focus here on the possible impact of GT alfalfa deregulation on the demand for alfalfa hay quality and leave the joint analysis of supply and demand impacts on prices and quantities for section 4.

The main possible impact of GT alfalfa deregulation on the domestic demand for alfalfa hay, conventional or organic, depends on the existence of a GE sensitive market among domestic consumers of alfalfa hay. If GT alfalfa is seen as an undesirable quality of alfalfa hay by some, these consumers will seek to substitute their purchases by: a) seeking imported non-GT alfalfa hay; b) seeking some form of GE-free certification; c) using GE-free hay based on other crops. In the case of GE sensitive consumers of conventional alfalfa hay, a fourth alternative would be to shift to organic alfalfa hay, or to certified conventional seeds that are able to guarantee that any presence of GT alfalfa is kept below certain levels.

In the case of alfalfa seed production, the impact of GT alfalfa deregulation on domestic demand will depend mainly on the impact of GT alfalfa deregulation on the demand for alfalfa for hay, since this is by far its main use.

Throughout our analysis of potential shifts in demand, we assume that presence of non-GT alfalfa occurs or is perceived to occur at a level considered relevant by the markets analyzed. If there is no presence or perception of presence of conventional and organic alfalfa by GT alfalfa, there is no impact on demand.

As demand for alfalfa hay is a derived demand from that for dairy, meat and other animal products, we first summarize the results of our analysis on the impact of GT deregulation on the demand for those products in downstream markets. This analysis is done in our Technical Report *Downstream Effects to Organic Production and Marketing of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix T).

### 2.2.2 *Impact on Downstream Demand*

In the above mentioned report, we analyze the impact of GT alfalfa deregulation on the demand for dairy, meat and other animal products, since alfalfa hay is used as an input in the production

of these products, as well as in the production of nutritional supplements for human consumption, in minor quantities.

The conclusions reached are summarized below.

In the case of downstream demand for conventional products:

- There is an ongoing trend of slow to moderate growth in demand for dairy products, driven mostly by population growth.
- In surveys, U.S. consumers often suggest a preference for non-GE foods;
- There is no evidence that any GE material in animal feed currently in use is actually transmitted to milk or meat;
- U.S. consumers show relatively little knowledge of their own consumption of GE products;
- Product labels in the United States typically do not indicate presence or lack of GE material;
- Other GE crops (e.g., corn, soybeans, canola) have been deregulated in the US for a number of years with no substantial drop in demand for conventionally produced dairy products or meat;

In the review done in our Technical Report *Downstream Effects to Organic Production and Marketing of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix T), we found no evidence to suggest that downstream domestic demand for conventional products is likely to be affected by GT alfalfa deregulation. Existence of a preference for GE-free products manifested in surveys may not translate to actual demand for various reasons, from the lack of GE presence in dairy and meat, to the lack of consumer information regarding GE presence in products consumed, to price differentials between non-GE and GE products.

In the case of downstream organic products we found that organic dairy represents nearly 90 percent of the total sales value of the combined US organic dairy and meat market in 2006. Thus, the dairy market is likely to be a more important downstream market for organic hay than is conventional dairy for conventional hay.

The establishment process of current U.S. standards for organic certification suggests a preference from organic consumers for non-GE products. However:

- Current organic standards do not allow for intentional use of GE feed, so any presence of GE traits in alfalfa used for feed in organic dairy or meat farms would be unintended;
- There is no evidence that any GE material in animal feed currently in use is actually transmitted to milk or meat;
- Consumer preferences for organic over GE foods are influenced in part by ethical and environmental factors that are likely unrelated to unintended presence of feed crops with GE material;

We found no evidence to suggest domestic consumers of organic dairy and meat would shift to substitute products in the event of possible unintended presence of GT alfalfa in feed for dairy and meat.

The above results must be interpreted with care. The absence of any indication of potential negative impacts of GT alfalfa deregulation on the domestic demand for downstream products does not mean that consumers or producers were not negatively impacted, but rather that shifts in domestic demand may not occur and sales of organic alfalfa may not be affected. We analyze other potential impacts in section 4.3.

### *2.2.3 Impact on Conventional Alfalfa Hay and Seed Domestic Demand*

Based on the findings summarized in section 2.2.2 above, we expect no to minor reductions in the demand for conventional alfalfa hay *that derive from no to minor declines in the demand for conventional dairy, meat, eggs, and other animal products*. Due to the minor nature of any negative impact, it is more likely to manifest as a slowing of domestic demand growth, if at all.

As noted in section 2.1.2 above, the demand for alfalfa seed derives from the demand for establishing new stands of alfalfa hay, and to a much lesser extent from the demand for alfalfa products destined for human consumption. It is reasonable to conclude that there will be no substantial impact on domestic conventional alfalfa seed demand *that is derived from shifts in demand for alfalfa for forage*.

There will, however, be shifts in demand for conventional alfalfa seed and conventional alfalfa hay induced by shifts in supply of high quality hay. This will be analyzed further below when we consider the impact of GT alfalfa deregulation on supply.

### *2.2.4 Impact on Organic Alfalfa Hay and Seed Domestic Demand*

To the extent that the demand for organic alfalfa hay is a derived demand, mainly from the demand for organic dairy, we found no evidence to suggest the demand for organic alfalfa hay will decrease with deregulation of GT alfalfa, *as a consequence of shifts in demand for organic downstream products*.

Given the disproportionately large share of organic dairy in the derived demand for organic alfalfa and the importance of alfalfa hay in dairy production it seems reasonable to expect that the demand for organic alfalfa hay will continue growing at a considerable pace, accompanying the growth in the demand for organic dairy.

There are, however, some possibilities of shifts up or down of the domestic demand of organic alfalfa hay. Given that the choice to produce organic products may not only be guided by market incentives but also by personal views of farmers, it is possible that some share of organic farmers may chose to abandon organic production if they feel that GE material has occurred in their seed or hay, or may potentially occur at levels they consider unacceptable. In this case, the demand for organic alfalfa hay would shift downwards. On the other hand, if there is any domestic GE

sensitive market for conventional alfalfa, GT alfalfa deregulation could lead consumers in this market to shift to organic alfalfa (as argued in 1.1.1). This would shift the demand curve upwards. As long as economic incentives prevail in the choice of producing alfalfa organically or not and as long as the GE sensitive domestic market among conventional alfalfa is small, neither of these possibilities should considerably alter the growth trend of the demand for organic alfalfa hay. As in the case of conventional alfalfa, there will likely be some shifts in demand caused by shifts in supply of conventional high quality alfalfa hay. We address this shift in section 3.

As previously noted, the demand for organic alfalfa seeds derives from the demand for organic alfalfa hay. Although the NOP requires the use of organic seeds to establish organic alfalfa stands, it is apparently common to use conventional seeds, given the often lack of organically grown seeds available. In this case, as the organic market is small relative to the conventional market, the impact of shifts in demand in the organic hay market will be likely little to non perceptible in the market for conventional seeds.

The potentially existing unfulfilled demand for organic alfalfa seed may be reinforced by GT alfalfa deregulation and may translate into greater pressure for the growth of organic varieties considered “equivalent” to the presently used conventional ones.

## 2.3 Summary of Findings

The domestic market for alfalfa hay was estimated to be approximately US\$ 8.8 billion in 2007. The domestic market for alfalfa seed was roughly US\$ 63 million in 2007. Alfalfa demand is a derived demand from that for dairy, meat, pet care and human consumption. Some sources indicate dairy is by far the main source of demand for alfalfa. We estimated dairy to be responsible for approximately half of the domestic demand, with meat production presumably consuming much of the rest. The demand for organic alfalfa seems to rely more heavily on dairy. While most of the seed used in organic alfalfa hay production is likely not organically produced, demand for organic alfalfa seeds, whether domestically produced or imported, is likely to grow in the near future.

We found no evidence that consumer sensitivity to GE products may translate into reduced demand for conventional or organic alfalfa hay with GT alfalfa deregulation. Pressure for organic or non-GE certification of alfalfa seeds for organic production may strengthen the current existing and potentially unfulfilled demand.

## 3.0 Impacts on Supply

### 3.1 Alfalfa Supply

In this section we focus on domestic production. Imports are more important for the domestic supply of alfalfa seed (imports have increased from 16% of domestic production in 1997 to 64% in 2007) than for alfalfa hay (0.1% of domestic production). Domestic production of hay is almost all destined to the domestic market, although the same cannot be said of seeds (roughly a third to a half are exported). We consider trade in our Impact on Trade Technical Report (appendix R).

#### 3.1.1 *Domestic Production of Alfalfa for Forage*

Production of alfalfa hay in the United States was in 2007 approximately 69.9 million tons, falling to 69.6 million tons in 2008 (USDA NASS, 2008b)<sup>73</sup>. This corresponds to almost half the production of hay in 2007 and 2008 (approximately 145 million tons for both years). Production statistics for haylage are not available for all states for 2007, but based on the 2002 and 2007 Agricultural Census and more recent USDA NASS data available for 18 states, haylage production adds another 10%-15% in alfalfa acres grown for forage.

Harvested acreage of alfalfa hay was in 2008 approximately 21 million acres (NASS, 2008b) for an average yield of 3.3 tons/ acre.

The alfalfa share of total hay production has been falling in the recent past, as has absolute production of alfalfa hay. In 2008 alfalfa production was at its lowest (69.6 million tons) compared to a high of 84.4 million tons in 1999.

---

<sup>73</sup> Including alfalfa hay mixtures.

Regarding geographic distribution, although alfalfa hay is grown most everywhere across the United States, it is most concentrated in the Midwest and Northwestern States. South Dakota has consistently devoted the most acres to alfalfa hay, with as much as 3 million acres of alfalfa hay in 2001.

**Table S-7. Alfalfa Hay Harvested Acreage by State (1,000 Acres), 2007**

| State        |      | State        |     | State          |     |

Source: Census of Agriculture, 2007

Approximately 83% of farms grew less than 100 acres of alfalfa hay and less than 18 percent of the farms accounted for 71 percent of the alfalfa production in 2007. Many farms may grow relatively small plots of alfalfa as an input for dairy or other farm industries, particularly for own consumption.

Intermediation between alfalfa hay growers and dairy farms seems to be done largely by individual brokers (often the hay or dairy farmers themselves) or by farmer associations, at least in California (Klonsky et al, 2007)

### *3.1.2 Domestic Production of Alfalfa Seed*

The latest complete information on alfalfa seed production comes from the 2002 Census of Agriculture. In 2007, approximately 62 million tons of alfalfa seeds were produced, compared to almost 58 million tons from the previous Census in 2002. Table S-11 below shows how this reflected largely an increase in acreage of harvested alfalfa for seeds.

**Table S-11. Alfalfa Seed Production and Acreage**

|                   | <b>2007</b> | <b>2002</b> |
|-------------------|-------------|-------------|
| Production (tons) | 62,115,239  | 58,020,460  |
| Acreage           | 121,467     | 110,617     |

Source: Census of Agriculture, 2007, 2002.

More frequent data is available for some states who report voluntarily to the NASS.

Source: USDA NASS, 2005, 2006, 2007. Numbers are rounded.

This data also show a fall in acreage dedicated to alfalfa seeds until 2002-2004 with some recovery in some states in recent years.

Mueller (2008) attributes recent reduction in alfalfa seed acreage in California to “changes in economics, environmental constraints, and regulatory issues.” Mueller (Undated a) lists among difficulties of alfalfa seed farming in California scarcity of water for crop irrigation and lack of development of new chemicals for insect control due to high registration costs

Production of seeds is largely concentrated in the Northwest. The top eight producing states are from that region.

Source: Census of Agriculture, 2007, 2002.

Mueller (Undated a) suggests California’s share of production has fallen in recent years and a larger share is coming from the Northwestern states. In 2007, US production of alfalfa seed came from 806 farms, about 70% from farms with over 250 acres of alfalfa seeds and 90% from farms with over 100 acres of alfalfa seeds.

Alfalfa seed constitutes a small portion of total alfalfa production in all of these states, though it appears to be more significant in California and Washington, making up between 3 and 7 percent of total alfalfa acreage from 2000-2007.

### 3.1.3 Domestic Production of Organic Alfalfa for Forage

There are no publicly available sources of data on US organic alfalfa production, so an estimate is derived here for illustrative purposes only. The USDA ERS reports that there were 411,342 acres on which organic hay (all types) was produced in 2005. According to the USDA NASS, 61,729,000 acres were in hay (all types) in 2005, of which 22,439,000 acres were in alfalfa hay in 2005. Thus alfalfa hay acreage is 36.35 percent of total hay acreage in 2005. In 2005 the national average yield per acre for alfalfa was 3.39 tons.

If we assume that the proportion of alfalfa hay to total hay acreage is the same for organic as for conventional, then we can estimate that  $411,342 \times 0.3635 = 149,526.2$  acres were in organic alfalfa hay in the US in 2005. Based on differences in organic and conventional alfalfa yield from Long et al. (2007), we get total US organic hay production in 2005 of  $149,526.2 \times 3.39 \times 0.875 = 443,532.1$  tons. By way of comparison, if instead one assumes that two-thirds of all organic hay is alfalfa (perhaps driven by demand from organic dairies requiring alfalfa rather than grass or some other type of hay), then we get total US organic hay production in 2005 of  $274,242 \times 3.39 \times 0.875 = 813,470$  tons. Based on these estimates, organic alfalfa hay production tonnage in 2005 may represent between 0.58% and 1.07% of total alfalfa production. These estimates are rough, however, and should only be used for illustrative purposes.

In terms of acreage, the number of acres devoted to growing organic alfalfa hay increased every year between 2000 and 2005, except for 2003. The share of all alfalfa hay acres that grew organic hay increased from 0.51 percent in 2000 to 0.92 percent in 2005.

**Table S-14. Organic Alfalfa Hay Harvested Acreage**

|                               | 2000    | 2001    | 2002    | 2003    | 2004    | 2005    |
|-------------------------------|---------|---------|---------|---------|---------|---------|
| <b>Acreage</b>                | 113,157 | 116,608 | 155,437 | 135,717 | 175,260 | 204,380 |
| <b>Share of Total Acreage</b> | .51%    | .49%    | .67%    | .58%    | .81%    | .92%    |

Source: USDA ERS, 2005; USDA NASS, 2007

Organic alfalfa hay production is distributed geographically similarly to conventional hay. However, production of organic alfalfa hay is more significant in proportion in some states than others. In 2005, for example, of all alfalfa hay acreage in Idaho, more than 4 percent was organic, compared to a national proportion of .92 percent.

**Table S-15. Geographic Distribution of Organic Alfalfa Hay Acreage (2005)**

| State        | Organic Acreage |
|--------------|-----------------|
| Idaho        | 49,497          |
| Wisconsin    | 29,389          |
| Minnesota    | 21,339          |
| North Dakota | 20,614          |
| South Dakota | 13,930          |
| California   | 13,246          |
| Iowa         | 9,193           |

|          |       |
|----------|-------|
| Colorado | 8,943 |
| Nebraska | 8,192 |
| Oregon   | 6,592 |

Source: USDA ERS, 2005

Organic alfalfa also seems to be grown in pockets, with 72 percent of organic acreage being found in just six states: Idaho, Wisconsin, Minnesota, North Dakota, South Dakota, and California (these six states only account for about 41 percent of total acreage).

### 3.1.4 Domestic Production of Organic Alfalfa Seed

There are no publicly available sources of data on US organic alfalfa seed production. To the extent that conventional alfalfa seeds are used in organic production (NOP permits in the lack of available organic seeds) a rough estimate of the production of seeds for the organic market follows. In section 3.1.3 it was estimated that US organic hay production in 2005 may range between 0.58% and 1.07% of total alfalfa hay production. If stand establishment demand for organic alfalfa seed (expressed as a percentage of total alfalfa seed demand from section 2.1.2) is roughly in the same proportion, then U.S. consumption of alfalfa seed for organic production in 2002 would range between \$300,700 and \$551,500. These demand estimates are rough and should only be used for illustrative purposes.

In section 2 we suggested that the production of organic alfalfa seeds may lag behind demand. This may be due to difficulties in producing organically the preferred varieties for organic alfalfa hay production, given the evidence we previously presented on complaints of non-availability of organic alfalfa seeds “equivalent” to the conventional ones used.

## 3.2 Impacts of GT Deregulation

### 3.2.1 Shifts in Supply

GT alfalfa deregulation will introduce a new cultivar that will compete with others in the conventional alfalfa seed and forage markets. As the main economic characteristics of the GT alfalfa cultivar are its reduced use of herbicide with potentially improved quality of alfalfa forage (reviewed in Technical Report *Changes in the Economics of Alfalfa Farming with Deregulation of Glyphosate-Tolerant Alfalfa* in appendix K) GT alfalfa will likely compete with the high quality alfalfa forage market. The domestic supply of conventional alfalfa for forage and conventional alfalfa seeds in the domestic market will then be impacted by GT alfalfa deregulation to the extent that the availability of GT alfalfa changes costs and returns to alfalfa farmers that choose to plant GT alfalfa.

The overall impact of the introduction of GT alfalfa in the market will be a shift downwards in the supply of alfalfa. This shift is caused by the reduction in average costs necessary to produce alfalfa of a given quality. This is represented in figure S-5 below and would imply a decrease in prices and increase in quantity of alfalfa sold, as dairy and meat farmers substitute alfalfa for other feeds.

**Figure S-5: Overall impact on supply of introduction of GT alfalfa**

Within the alfalfa market, however, there are segments: conventional and organic, domestic and international, high and low quality alfalfa and possibly GE sensitive and non-GE sensitive. The impact of GT deregulation on each of these segments will not be the same. There are two main possible sources of shifts in supply introduced by GT alfalfa deregulation:

- 1) Changes in production costs for those adopting GT alfalfa
- 2) Changes in production costs for those not adopting GT alfalfa and that are associated with presence of GT alfalfa material in non-GT alfalfa (cross-contamination or gene flow).

The supply of organic alfalfa hay and organic alfalfa seeds will not be directly affected by changes in cultivar adoption. Organic alfalfa growers cannot adopt GT alfalfa because GE crops may not be certified as organic. Organic certification may also not be affected given that presence of GE material is tolerated by organic certification that presently does not test for GE material and focuses on process rather than on product. However, to the extent that conventional and organic alfalfa are substitutes, a decrease in the price of conventional alfalfa will affect the demand of organic alfalfa.

Shifts in domestic production may or may not be partially offset by imports. We leave any analysis of impacts on imports for another report and assume for now that there is no change in imports of alfalfa.

Throughout this section we do not analyze shifts in demand, but assume there is some demand for GE-free alfalfa. Although we have not found much evidence of this demand in analyzing the domestic market, we expect this will be the case of export markets.

We analyze the impact of each possible sources of shifts in supply below.

### 3.2.2 Impacts on Supply from Adoption of GT alfalfa

Changes in production costs for those adopting GT alfalfa were reviewed in our Technical Report *Changes in the Economics of Alfalfa Farming with Deregulation of Glyphosate-Tolerant Alfalfa* (Appendix K). We argued that, at least in the short run (during the planning horizon of the life of a stand) there were likely higher returns to be expected from GT alfalfa hay as compared to conventional alfalfa hay, given potential improvements in hay quality (lesser weed content). We did not have enough information to draw any conclusions regarding costs and returns in alfalfa seed production.

We suggested in section 3.2.1 that the overall impact on supply of the introduction of GT alfalfa would be a reduction in prices and an increase in quantities of alfalfa sold in the marketplace. As noted, however, the alfalfa market is segmented in various ways and the impact on producers of various alfalfa varieties and for various markets will not be the same.

We analyze the impact of shifts in supply in the various alfalfa market segments below. In doing so, we should not lose sight of the fact that the sum of the supply of alfalfa in the various markets will add to the total alfalfa supply. Thus, shifts in supply in one segment are likely to be compensated by shifts in supply in another to the extent that they add up to the total supply shift suggested in section 3.2.1.

In the case of those adopting GT alfalfa for forage, a reduction in costs of production of GT alfalfa as compared to conventional alfalfa, or an equivalent improvement in quality of alfalfa forage for a given production cost will have the impact of a shift down in the supply curve in the market for high quality alfalfa forage with reduction in prices and increases in quantities bought and sold in the market

**Figure S-6: Impact of adoption of GT alfalfa on the market for high quality alfalfa forage**

Despite no shift in the demand curve, the quantity of alfalfa forage of high quality demanded in the market increases given the lower prices induced by the production of GT alfalfa and its consequential shift in the supply curve. How much the price will fall and how much the quantity of high quality alfalfa sold will increase, we do not know. This depends on the extent to which the demand curve is sensitive to decreases in prices, that is, the inclination of the demand curve portrayed in figure S-6 (price-elasticity of demand).

The reduction in the price of high quality alfalfa hay will likely have an impact on the demand for alfalfa hay of lower quality, as well as on the demand for alfalfa hay of high quality that is only available at higher costs (non-GT alfalfa). To the extent that high quality and low quality (or higher cost) alfalfa hay are substitutes, a reduction in the price of high quality alfalfa hay shifts the demand for low quality alfalfa hay downwards.

The supply curve may or may not shift upwards. If only farmers already producing high quality alfalfa adopt GT alfalfa, there will be no change in the supply curve of low quality alfalfa. However, if adoption of GT alfalfa is widespread, farmers currently producing low quality alfalfa will also adopt GT alfalfa and the supply curve of low quality alfalfa will move upwards.

Figure S-7 illustrates these movements. The result is clearly a reduction in the quantity of low quality alfalfa commercialized in the marketplace. The impact on prices, though, is undetermined and will depend on the magnitude of change of each factor described above, as well as on the sensitivity of the demand and supply curves to prices (price elasticity of supply and demand).

**Figure S-7: Impact of adoption of GT alfalfa on the market for low quality alfalfa forage**

The organic alfalfa hay market may suffer a similar shift in its demand as does the low quality alfalfa hay market. This would happen under two possible scenarios.

- (3) If organic dairy and meat farmers will consider shifting to conventional farming in the face of the decreased costs of high quality conventional alfalfa (and presumably increased returns);
- (4) If the decreased costs of high quality conventional alfalfa are transmitted to conventional dairy and meat costs, increasing the price differential between conventional and organic

dairy and meat, stimulating organic dairy and meat consumers to purchase conventional products.

We have no evidence on the likelihood that the first scenario will occur. To the extent that organic farmers have chosen organic production out of philosophical values, the economic incentive to switch to conventional farming should not have an impact. The likelihood of the second scenario is also not clear. In our Technical Report *Downstream Effects to Organic Production and Marketing of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix T), we argue that governmental intervention in the pricing of milk and the low share of alfalfa in total meat production cost suggest the transmission of lower alfalfa costs to prices of conventional dairy and meat should be minor.

The remaining analysis in this chapter considers the case in which a downwards shift in demand for organic alfalfa does occur to some extent, since this is a scenario of particular concern to organic farmers. Figure S-8 reflects the shift in demand for organic alfalfa.

**Figure S-8: Impact of GT alfalfa adoption on organic alfalfa for forage**

In the case of alfalfa farmers producing GT alfalfa for seed, we were not able to find sufficient information on the returns in the production of conventional alfalfa seed as compared to the production of GT alfalfa seed in our Technical Report *Changes in the Economics of Alfalfa Farming with Deregulation of Glyphosate-Tolerant Alfalfa* (appendix K). It is likely that, given sufficient time, there will be no distinction in market returns to alfalfa seed producers for those agreeing to produce GT varieties or other varieties, and that any monopolistic rents will benefit the plant breeding company that has the property right to those varieties. However, there could be transitory effects, if there is demand for GT alfalfa seeds from alfalfa forage producers that is not being met by a corresponding increase in GT alfalfa seed production. In this case, returns to GT alfalfa seed producers could be higher than for producers of other varieties during a period of adjustment in the market.

### 3.2.3 Impacts on Supply from Presence of GT alfalfa

Changes in production costs and returns for those not adopting GT alfalfa are associated with the presence of GT alfalfa in non-GT alfalfa material. Non-GT alfalfa farmers may be a subset of either the high or low quality alfalfa segments considered above, or a subset of both these segments.

Changes in costs associated with the presence of GT alfalfa in non-GT alfalfa material must assume there is some market for GE-free alfalfa, whether domestic or foreign, whether having zero tolerance or accepting some degree of presence. If there is no such market, GT alfalfa stands treated as conventional or organic will perform similarly to other varieties and we expect no impact on costs and returns.

By presence of GT alfalfa in non-GT alfalfa material, we mean both comingling (no exchange of genetic material, e.g. same equipment used for GT and non GT alfalfa and equipment was not properly cleaned) or gene flow (through cross-pollination). The literature we found focuses on gene flow and we understand this reveals a lesser concern for comingling. Van Deynze et al. (Undated) argue that “best practices in the cleaning and management of seed harvesting and processing equipment are effective in managing admixtures between GE and conventional alfalfa seed.”

The extent of presence – number of acres or tons of non-GT alfalfa hay and seed that will be contain GT alfalfa every year in a scenario of GT alfalfa deregulation – will depend on:

- a) *Gene flow.* Gene flow is defined as “the incorporation of genes into the gene pool of one population from one or more other populations” (Putnam, 2007). We review the current U.S. research on gene flow in alfalfa in a separate Technical Report (appendix Q). Gene flow depends on many factors including stewardship. In that report we conclude that Forage Genetics International’s Best Practices are expected to maintain the presence of GT alfalfa at a rate considerably below 0.5 percent, within some distance from the areas of adoption of GT alfalfa<sup>74</sup>, although the role of feral alfalfa as a possible reservoir for the GT trait and its role in GT alfalfa population dynamics may require further exploration;
- b) *Geographic distribution of adoption of GT alfalfa.* If adoption rates were high but concentrated in certain regions of the country, this would increase the possibility that locations would be available for production of GE-free alfalfa that would be beyond the reach of gene flow from GT alfalfa. In the case of hay, this is highly unlikely. As previously noted, alfalfa hay production is distributed throughout much of the country. On the other hand, gene flow to alfalfa hay is considered relatively unlikely. In the case of alfalfa seed, the likelihood of gene flow is greater. However, production is not dispersed throughout the country, but rather concentrated in areas where the climate is favorable, mostly in Western States. The feasibility and benefits of isolating areas for production of non-GT alfalfa seed are thus likely to be greater for seeds. If this were possible, however, it would come at a cost. The cost would be either that of creating

---

<sup>74</sup> Forage Genetics International’s validation study of its own Best Practices, used isolation distances from 900 feet (the minimum isolation distance in their Best Practices) to “more than 10 miles” (Forage Genetics International, 2007) during the 2006 growing season. The longest distance in which gene flow was observed in that study was 2.75 miles from a GT alfalfa seed field where 0.008% of conventional seed fields presented GT traits (standard error of 0.006).

extended buffer zones or of relocation of alfalfa seed production. These costs would translate into higher land rents. As shown in our Technical Report *Changes in the Economics of Alfalfa Farming with Deregulation of Glyphosate-Tolerant Alfalfa* (appendix K), land rents are a considerable cost of seed production;

- c) *Geographic distribution of non-GE production.* Of particular interest is the geographic distribution of production for GE sensitive markets. If the location of alfalfa production for forage and for seed destined to GE sensitive markets is concentrated, it would be presumably easier to distance this sensitive production from that of GT alfalfa. In our review of the domestic demand for alfalfa in section 2 we found no evidence that some portion of it is likely to be sensitive to GT alfalfa. Sensitivity to GE traits in export markets has not yet been analyzed and will be considered in depth in our Technical Report *Impacts to United States Trade of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix R).

In addition, the rate of adoption of GT alfalfa will have an impact on the number of years it will take for the level of GT alfalfa in the marketplace to reach the levels anticipated in non-GT alfalfa.

There are two ways in which presence of GT alfalfa in non-GT alfalfa material may affect producer costs and returns, given an existing demand for GE-free alfalfa:

- a) *Loss in production.* If producers cannot avoid GT alfalfa material above those levels found acceptable by the market, any alfalfa seeds or forage previously destined to those markets will have to be shifted to salvage markets that may pay a lower price.
- b) *Avoidance costs.* If producers can avoid the accidental presence of GT alfalfa, whether through adopting buffer zones, relocating to non-deregulated areas (if deregulation was not done on a national level), or requiring testing for GT alfalfa traits in alfalfa seeds used for production, there is a cost of avoidance that must be incorporated into its production costs.

In either case, the impact on supply is best understood by imagining two separate market segments: a GE sensitive market and a non-GE sensitive one. In analyzing shifts in these separate market segments, we should keep in mind that the sum of supply in these segments will add up to the supply of non-GT alfalfa that is in turn a share of total alfalfa supply.

If there is loss in production destined to the GE sensitive market or an increase in costs of supplying that market, the supply curve for that market will shift upwards. If non-GT alfalfa material containing GT-alfalfa is then destined to the non-GE sensitive market (loss in production) or if some farmers are not able to continue supplying the existing market given the increased costs and shift to the non-GE sensitive market (avoidance costs), the supply curve for that market will shift downwards. These shifts are illustrated in figure S-9 below.

**Figure S-9: Impact of unintended presence of GT alfalfa**

In the case of the supply of alfalfa seeds for organic production, avoidance costs may result from pressure for new organic seed requirements – such as seed certification – for organic alfalfa hay production, as a means of guaranteeing the presence of GT alfalfa is below a desired threshold.

### 3.3 Summary of Findings

Production of alfalfa hay in the United States was in 2007 approximately 72.6 million tons, while that of seeds was in 2007 approximately 62 million tons. Production of alfalfa hay is distributed in much of the United States while seed is highly concentrated in Northwestern states. The alfalfa share of total hay production has been falling in the recent past, as has been the absolute production of alfalfa hay. Organic alfalfa hay acreage was quickly approaching 1% of total alfalfa hay acreage in 2005. Domestic production of organic alfalfa seed seemed to be lagging behind.

GT alfalfa deregulation is likely to impact the supply of conventional alfalfa in at least two ways. First, there will be a reduction in the supply of conventional low quality/high cost (non-GT) alfalfa hay as producers adopt GT alfalfa. Second, the potential of GT alfalfa to be present in non-GT alfalfa material will move the supply of alfalfa for GE sensitive markets even further upwards, while it will bring some supply back to the non-GE sensitive market, only partially compensating for the initial reduction in supply.

In the case of organic alfalfa, assuming some GE sensitivity in domestic organic markets, presence of GT alfalfa in non-GT material may reduce the supply of organic alfalfa for GE sensitive organic markets with a possible increase in supply for non-GE sensitive organic markets.

## 4.0 Impacts on Conventional and Organic Alfalfa Farmers

### 4.1 Impacts on Non-GT Alfalfa Farmers

In section 2 we argued that GT alfalfa deregulation is likely to have little to no impact on domestic demand of conventional alfalfa, *derived from downstream demand*. However, in Section 3 we noted that GT alfalfa deregulation will likely have a negative impact on the demand of low quality or high cost (non-GT) alfalfa to the extent the increased supply of GT alfalfa with high quality forage and lower costs reduces the demand for substitute varieties. The result will be a downward shift in demand for non-GT alfalfa.

On the supply side, there are at least two different effects. First, there will be a reduction in the supply of conventional low quality/high cost (non-GT) alfalfa hay as producers adopt GT alfalfa. Second, potential presence of GT alfalfa in non-GT alfalfa material will move the supply of alfalfa for GE sensitive markets even further upwards, while it will bring some supply back to the non-GE sensitive market, only partially compensating for initial reduction in supply. The results are shown in figure S-10 below. The move upwards in the supply curve is larger for GE sensitive markets than for non-GE sensitive ones.

**Figure S-10: Impact on non-GT alfalfa farmers**

What figure S-10 shows is that non-GT farmers producing for GE sensitive markets are likely to lose more markets than non-GT farmers producing for non-GE sensitive markets. In either case, whether the resulting market prices for non-GT alfalfa will be higher or lower than pre-deregulation prices for low quality alfalfa, we cannot say, but prices in GE sensitive markets will be likely higher than in non-GE sensitive markets.

In section 2 we found no evidence of a domestic GE sensitive market for conventional alfalfa. In this case, the resulting impact will look like the non-GE sensitive market in figure S-10. The market for non-GT alfalfa will be reduced as farmers switch to producing GT alfalfa and demand for non-GT alfalfa falls. The resulting final price for non-GT alfalfa is not clear but it will likely be lower than it otherwise would, pushed down by the lower cost of its substitute: GT alfalfa. During a period of adjustment to the new market segmentation between GT alfalfa and non-GT

alfalfa, prices will tend to fall if demand shifts faster than farmers, or will tend to rise if farmers shift faster than demand.

A numerical estimation of the impact of GT alfalfa deregulation on the non-GT alfalfa market under this scenario would require being able to estimate:

- a) What the level of adoption of GT alfalfa is;
- b) What is the sensitivity of the demand curve to increases in prices (the price-elasticity of demand) since this will determine how much the price of non-GT alfalfa will increase as producers shift to GT alfalfa reducing supply;
- c) The sensitivity of low quality alfalfa demand with respect to a reduction in price of high quality alfalfa (cross-elasticity) since this will determine how much the demand curve for low quality alfalfa will shift downward
- d) What is the sensitivity of the supply curve to increases in prices (the price-elasticity of supply) since this will determine how much the price of alfalfa will fall as demand shifts to GT alfalfa;

We do not have sufficient information to provide any reliable numerical estimate.

The market for seed will likely follow the tendency of the market for alfalfa hay, since it is a derived demand. In the case of seeds, reductions in supply are likely to considerably raise prices since the price-elasticity of demand seems to be very low. Myer et al. (1998) use panel data from seven states and conclude that the demand for alfalfa seed is highly inelastic. This is to be expected given the importance of appropriate seed choice for alfalfa hay yields and quality and the relatively low share of total production costs represented by seeds.

## 4.2 Impacts on Organic Alfalfa Farmers

In section 2 we explain that we found no evidence that GT alfalfa deregulation would directly cause a shift in the demand for organic alfalfa hay. However, in section 3 we argued that the demand for organic alfalfa could shift downwards with the reduction in costs of conventional hay, to the extent that organic and conventional farming are substitutes or to the extent that the reduction in conventional alfalfa hay costs are transmitted to prices of conventional dairy and meat..

On the supply side, unintended presence of GT alfalfa in non-GT alfalfa material would have the effect shown in figure S-9: a reduction in supply for GE sensitive organic markets with a possible increase in non-GT sensitive organic markets. This result, however, relies on the assumption that some degree of GT sensitivity exists in domestic organic markets.

As we have not been able to find any evidence of GT sensitivity of demand in domestic organic markets, we first consider the case in which the only impact of GT alfalfa deregulation is the demand reduction that follows the reduction in prices of conventional GT alfalfa. We also consider what the impact would be in case there actually was GT sensitivity of domestic organic demand.

With no GT sensitivity of demand, the only impact on organic markets is the downward shift in demand that follows the reduction in prices of conventional alfalfa. This is portrayed in figure S-8 and reproduced again below.

**Figure S-11: Impact of GT alfalfa adoption on organic alfalfa for forage with no GT sensitive domestic markets**

To estimate numerically the impact for organic farmers under this scenario, we need to know:

- a) The magnitude of the decrease in prices expected of conventional alfalfa;
- b) The cross-elasticity of demand between conventional and organic alfalfa. This will tell us how much the demand for organic alfalfa will fall in response to the decrease in prices of conventional alfalfa;
- c) The price-elasticity of supply of organic alfalfa. This will tell us how much organic market quantities and prices will fall in response to the shift in demand downwards.

We do not have sufficient information to provide any reliable numerical estimate.

In the case of any GT sensitivity in the domestic organic market, the reduction in demand will be complemented by the shifts in supply shown in figure S-9. The result of these shifts is shown in figure S-12 below.

**Figure S-12: Impact of GT alfalfa adoption on organic alfalfa for forage with GT sensitive domestic markets**

The result of GT alfalfa deregulation under this scenario depends on the extent of the GT sensitive market within the organic market. The larger the GT sensitive market is, the more likely quantities sold will fall, although with unclear effect on prices. The larger the non-GT sensitive market is, the more likely prices will fall but with unclear effect on quantities.

Once again, we do not have enough information to estimate numerically the impact for organic farmers under this scenario. In addition to the elasticities of supply and demand we would need to know the share of the organic market that is GT sensitive and the magnitude of the decrease in prices expected for conventional alfalfa.

### 4.3 Distributional and Social Impacts

GT alfalfa adoption by farmers, presence of GT alfalfa in non-GT alfalfa fields, and the demand response to GT alfalfa deregulation will have several distributional and social impacts:

*Businesses lost and gained.* In our above discussion we mentioned that farmers adopting GT alfalfa will likely face decreased costs or improved markets while organic farmers may face a reduction in demand. Early GT alfalfa adopters may gain markets while conventional non-GT alfalfa farmers producing high quality alfalfa may lose, due to potentially higher costs when compared to GT alfalfa. Organic farmers most affected by the presence of GT alfalfa may lose markets while organic farmers less affected may gain, if there is GT sensitivity in the market for organic alfalfa.

*Market Structure.* Increased land costs that may affect non-GT alfalfa farmers attempting to avoid GT alfalfa. This may benefit larger alfalfa farmers. In our Technical Report *Changes in the Economics of Alfalfa Farming with Deregulation of Glyphosate-Tolerant Alfalfa* (appendix K) we showed that land costs are a major factor in generating economies of scale in alfalfa grown for forage, and we also showed that land costs are a major cost factor in alfalfa seed production.

The impact of increased land costs on seed production will likely be mitigated by the fact that the elasticity of demand for seed seems to be highly inelastic. In other words, as seed quality is

important for alfalfa forage producers and seed costs are a small part of their total production costs, increases in seed costs should not significantly affect sales of seed.

If adoption rates of GT alfalfa are high, alfalfa seed farmers will face increased demand for GT alfalfa seed and will shift to production of this variety. There will likely be an increased market concentration in the supply of alfalfa seed technology.

To the extent that organic farming is more suitable for small farms than conventional farming (less economies of scale related to greater dependency of labor), a reduction in the demand for organic products may favor larger farmers.

*Distribution of Costs of Loss of Production and Avoidance.* To the extent that there is presence of GT alfalfa in the organic market, we argued that producers would bear a cost in either loss of production or measures (typically land costs) to reduce the likelihood of unintended presence of GT alfalfa.

Organic certification typically requires producers to take measures to avoid pesticide contamination or the unintended presence of GE material from conventional farming. However, who should bear the costs of preventing the unintended presence of GT alfalfa in non-GT alfalfa material is debatable. Movement of GT alfalfa into non-GT alfalfa fields would be considered an externality in economics: a cost to third parties of producing GT alfalfa that is not being internalized in the cost of production of GT alfalfa.

*Social aspects of organic farming.* In section 2 we noted that we were unable to identify a GT sensitive domestic demand for organic products. This does not mean that GE products are welcome by organic consumers, but rather any sensitivity to GE products will likely not translate into a decrease in sales of organic alfalfa. Organic producers (and consumers) may still be unhappy with the outcome. To the extent that organic farming involves broader life choices related to philosophical attitudes, this discontent is a negative impact.

This situation may conceal a market for GE-free products in need of development.

#### 4.4 Summary of Findings

The impact of GT alfalfa deregulation on non-GT conventional alfalfa farmers will likely be a reduction in the market for non-GT alfalfa as farmers switch to producing GT alfalfa and as the demand for non-GT alfalfa falls. The resulting final price for non-GT alfalfa is not clear but it will likely be lower than the present prices, pushed down by the lower cost of its substitute: GT alfalfa. During a period of adjustment to the new market segmentation between GT alfalfa and non-GT alfalfa, prices will tend to fall as the demand shifts faster to GT alfalfa than farmers, or will tend to rise if farmers shift faster than demand.

The impact of GT alfalfa deregulation on organic alfalfa farmers depends on whether there is a GE sensitive share of the domestic organic alfalfa markets. With no GT sensitivity of demand, the only impact on organic markets is the downward shift in demand that follows the reduction in

prices of conventional alfalfa, leading to a reduction in prices and quantities sold domestically of organic alfalfa. In the case of GT sensitivity of demand in organic alfalfa markets, the result of GT alfalfa deregulation depends on the extent of this GT sensitivity: the larger the GT sensitive market is, the more likely quantities sold will fall, although with unclear effect on prices. The larger the non-GT sensitive market is, the more likely prices will fall, but with unclear effect on prices.

GT alfalfa adoption by farmers, presence of GT alfalfa material in non-GT alfalfa fields, and the demand response to GT alfalfa deregulation will have several distributional and social impacts: the loss and gain of businesses, changes in market structure, distribution of the costs of loss of production and avoidance in GT sensitive markets, and potential negative impacts on the environment preferred by organic farmers (one free of GE products).

## Appendix S-2. Literature Search

### 1.0 Literature Search Strategy

Most data was obtained from USDA websites.

Much of the remaining information was obtained from university (and cooperative extension) linked alfalfa portals and alfalfa symposium proceedings such as:

- The California Alfalfa Workgroup: <http://alfalfa.ucdavis.edu/>
- The University of California Alfalfa Seed Production Homepage: <http://alfalfaseed.ucdavis.edu>
- University of Wisconsin Forage Research and Extension: <http://www.uwex.edu/ces/forage/>
- 2007 37<sup>th</sup> California Alfalfa and Forage Symposium: <http://alfalfa.ucdavis.edu/2007AlfalfaConference>
- 2006 Western Alfalfa and Forage Conference: <http://alfalfa.ucdavis.edu/2006AlfalfaConference>
- San Joaquin University of California Cooperative Extension: [http://cesanjoaquin.ucdavis.edu/Agriculture/Publications,\\_Research\\_Reports.htm](http://cesanjoaquin.ucdavis.edu/Agriculture/Publications,_Research_Reports.htm)

Other papers were obtained from internet searches; others from academic journals such as *Agronomy Journal* and *Agribusiness*.

Some of the conclusions are based on our Technical Report *Downstream Effects to Organic Production and Marketing of Deregulation of Glyphosate-Tolerant Alfalfa*.

Direct personal communication with extension experts was also used and is detailed in the References.

## Appendix S-3. Probability of Alfalfa Seed Acres Using Herbicide

One policy option to address the impacts of presence of GT alfalfa material in non-GT alfalfa is to guarantee the possibility of producing non-GT alfalfa seeds at a distance from GT alfalfa sufficient to reduce the likelihood of unintended presence to virtually zero.

In this appendix we build on the exercise constructed in our Technical Report *Changes in the Economics of Alfalfa Farming with Deregulation of Glyphosate-Tolerant Alfalfa* (appendix K). By listing U.S. counties that currently produce alfalfa seed by acreage and multiplying this acreage by the likelihood of an acreage in that county not having alfalfa grown for forage with herbicides, we obtain a ranking of counties that could produce alfalfa seeds while losing relatively little by not being able to adopt GT alfalfa hay. The process for obtaining this ranking was as follows:

1. We listed all U.S. counties for which alfalfa seed is grown and ranked them by alfalfa seed acreage. The ranking by acreage is taken as an indicator of economic interest in producing alfalfa seed.
2. We listed our ranking of counties growing alfalfa for forage with herbicide, as presented in the Technical Report *Changes in the Economics of Alfalfa Farming with Deregulation of Glyphosate-Tolerant Alfalfa* (appendix K), and subtracted the values from that ranking from 1: this gives us the likelihood of randomly selecting an acre in a county that does not have alfalfa grown for forage with herbicide use.
3. We multiplied the two lists above to obtain a ranking of counties with economic interest in producing alfalfa for seed, while relatively little in producing alfalfa for forage with herbicide.

The ranking is presented below.

The top counties are also counties that actually do produce considerable acreage of alfalfa for forage under herbicide. This reflects the fact that there are counties that produce both seed and forage with intense use of herbicide. Other counties with relatively low likelihood of alfalfa grown for forage under herbicide may find it in their interest to give preference to growth of alfalfa seeds under special conditions, if these conditions generate particularly high returns, as those that may be obtained by the exploration of specialized niche markets.

**Table S-16. Probability of Acres in Alfalfa Seed not in Hay with Herbicide**

| <b>Geographic area</b> | <b>Harvested Acres of Alfalfa Seed</b> | <b>Acres in Farm</b> | <b>% of Seed Acres to Total Farm Acres</b> | <b>% Acres low-alfalfa, low herbicide use</b> | <b>% High rates alfalfa seed w/ low rates alfalfa hay and herbicide use</b> |

Production and Marketing of  
Deregulation of Glyphosate-Tolerant  
Alfalfa**

# **Downstream Effects to Organic Production and Marketing of Deregulation of Glyphosate-Tolerant Alfalfa**

## **Executive Summary**

There is a trend of moderate overall growth in downstream markets for conventional alfalfa and stronger growth in organic downstream markets.

The deregulation of glyphosate-tolerant (GT) alfalfa may affect organic and conventional dairy, meat, livestock and pet care domestic markets in two ways: a) through reduced demand; b) through reduced costs/ improved quality of feed. The latter could have impacts on the price differential between organic and conventional dairy and meat products, since organic production cannot make use of improved quality GT alfalfa.

Although there is evidence of some claimed consumer preference for foods free of genetically engineered organisms in the United States, we found no evidence that deregulation of GT alfalfa may translate into reduced demand in downstream markets. There is actually a possibility that the demand for organic foods may increase as consumers concerned with genetically engineered foods may switch to organic products.

Expected lower prices/ higher quality of alfalfa hay will likely benefit dairy farmers and to a lesser degree cow-calf production.

The reduced costs in dairy farming and cow-calf production may not be transmitted to dairy and meat products, however, because of price regulation in dairy markets and the low share of alfalfa production costs in the case of meat production.

## 1.0 Introduction

### 1.1 Scope of Report

This report analyses the potential impact on downstream markets of the deregulation of glyphosate-tolerant (GT) alfalfa. Main downstream markets are those for dairy, meat, livestock and pet care. The report is limited to domestic downstream markets, and impacts on foreign markets are left for the Technical Report *Impacts to United States Trade of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix R).

Below we explain the methodology upon which this analysis is based. In section 2 we focus on the impact of GT deregulation through GT sensitivity of demand in downstream markets. In section 3 we focus on the impact of GT deregulation through reduced production costs and substitution effects.

### 1.2 Methodology

Some alfalfa is produced for human consumption. In our Technical Report *Economic and Social Impacts to Conventional and Organic Farmers of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix S) we argue that alfalfa for human consumption, whether for sprouts or in the form of leaves for dietary supplements, is likely a very small portion of total demand for alfalfa and thus is not included in the analysis.

Honey is also produced from alfalfa fields. However, in our Technical Report *Economic and Social Impacts to Conventional and Organic Farmers of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix S) we argue that honey production does not generate an actual “demand” for alfalfa to the extent that alfalfa producers pay honey producers for use of honeybees in alfalfa pollination and not the other way around. This suggest any impact of alfalfa on honey producers will have a small effect on honey production and that producers are likely to have access to good substitutes for alfalfa as a sources of nectar for honeybees<sup>75</sup>. We thus also do not include any analysis of honey markets in this report.

Alfalfa downstream markets are mainly those for dairy, beef, livestock and pet care, and alfalfa is by far mainly used for forage, whether in the form of hay or haylage, as well as processed in meal and pellets for animal feed. We thus focus on the dairy, beef, livestock and pet care downstream markets. Alfalfa processors are not treated as a separate market to the extent that they are intermediaries between alfalfa producers and dairy, beef or livestock producers.

#### 1.2.1 Assumptions

GT alfalfa production is assumed to potentially affect organic and conventional dairy, meat, livestock and pet care domestic markets in two ways<sup>76</sup>:

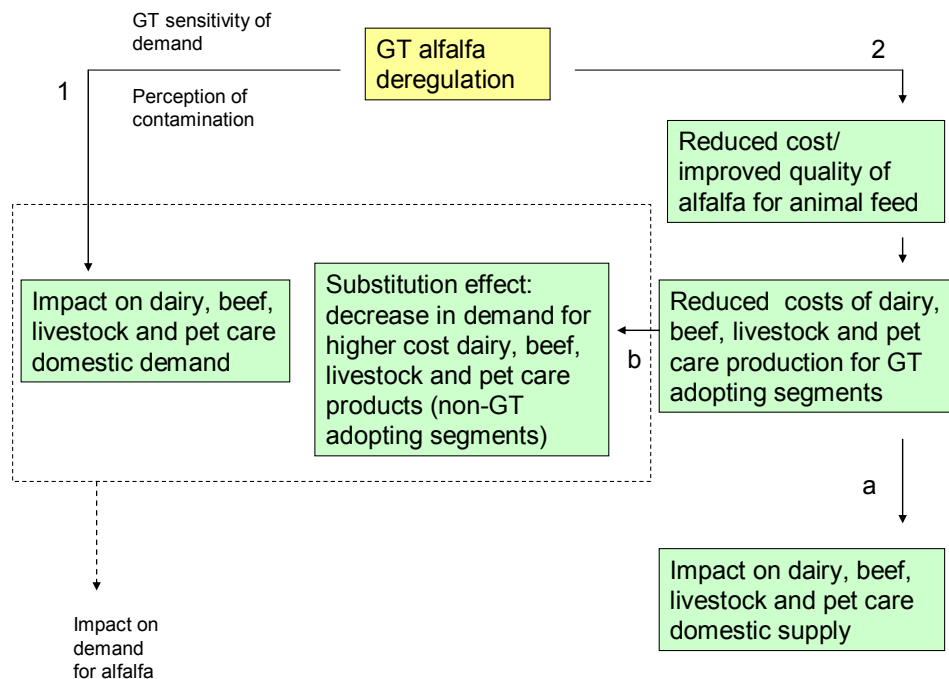

---

<sup>75</sup> Although there may be some impact on the income of honey producers to the extent that these producers count on pollination as a source of income.

<sup>76</sup> In this report, conventional dairy, meat, livestock and pet care products are those produced with conventional or GT alfalfa. Organic dairy, meat, livestock and pet care products are those where any alfalfa used is organic. When a distinction is needed in conventional downstream markets, among production systems using or not GT alfalfa, this distinction will be made explicit by expressions such as “GT adopting segments, ” or “GMO free” products.

1. To the extent that the domestic demand for downstream products is sensitive to the presence of genetically engineered (GE) organisms and to the extent that there is a perception of presence of GE material in downstream products, the domestic demand for dairy, meat, livestock and pet care will be affected;
2. Reduction in costs/ improvements in quality of alfalfa through the adoption of GT alfalfa will affect downstream markets to the extent that alfalfa production cost changes are transferred to the price of alfalfa. Production costs of some downstream market segments utilizing alfalfa will decrease (those segments adopting GT alfalfa). This will have two possible impacts:
  - a. The supply curve of dairy, beef, livestock and pet care will shift downwards, with potential increases in quantities produced and decreases in prices.
  - b. To the extent that decreases in production costs of some downstream market segments are reflected in decreased prices, consumers will substitute dairy, meat, livestock and pet care produced at lower prices for dairy, meat, livestock and pet care producers at higher costs.

These assumptions are illustrated in figure T-1 below:

**Figure T-1: Deregulation impact on downstream markets**

The dashed lines represent the downstream impacts that will affect the demand for alfalfa. These impacts were incorporated in the analysis done in the Technical Report *Economic and Social*

*Impacts to Conventional and Organic Farmers of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix S).

In section 2 we focus on the impact of GT deregulation through GT sensitivity of demand in downstream markets (labeled “1” in the figure above). In section 3 we focus on the impact of GT deregulation through reduced production costs and substitution effects (labeled “2” in the figure above).

### *1.2.2 Data and Information Sources*

Our basic data were obtained from USDA sources, under the assumption that these are the best quality agriculture statistics available. These data were complemented with information obtained from articles, typically of an academic nature and peer-reviewed whenever possible, under the assumption that these documents are subject to standards that should help reduce if not eliminate any intentional bias.

## 2.0 Impacts of Sensitivity to GE Organisms

Demand in downstream markets will be impacted by deregulation of GT alfalfa to the extent that some consumers will seek to avoid consumption of dairy and meat (and egg products) from animals fed GT alfalfa, or to avoid feeding livestock and pets with GT alfalfa. The result may be a reduction in demand for dairy, meat and livestock and pet feed that is not produced using organic production methods, due to the likelihood of these goods having been produced with GT alfalfa. This could result in an increase in demand for similar goods believed to be largely or completely free of GE content, such as goods produced using organic production methods. This could take various forms.

One form would be an increase in imports from countries where GT alfalfa is not used.

A second form could be a shift towards organic production if this is perceived as at least free of intentional use of GT alfalfa. The demand for organic products in downstream markets, however, may also be negatively affected if consumers perceive the possibility of GT alfalfa being present in organically produced products.

A third possibility would be increased pressure for the development of new niche market certification standards for foods free of any GE content. This type of niche market is more likely to develop:

- a) the more costly it is to shift to other substitutes (e.g., other forms of animal feed) that do not include GE material;
- b) the less costly it is to produce goods with equivalent quality characteristics for the niche market that are completely or largely free of GE material, whether through domestic production or through imports.

If both a) and b) are costly, consumers sensitive to GE products may still find themselves reluctantly consuming GE products.

In section 2.1 we consider current trends in alfalfa downstream markets. In section 2.2 we consider the possible impacts, as outlined above.

### 2.1 Trends in Downstream Demand

#### 2.1.1 *Dairy*

Consumption of dairy products in the United States has grown steadily in the last 20 to 30 years at rates above population growth thanks to increases in per capita consumption (LaDue et al, 2003). There has been actually a decrease in per capita consumption of fluid milk, more than compensated by an increase in per capita consumption of cheese.

U.S. per-capita consumption data for all dairy products (calculated on a milk equivalent basis) are given in table T-1 below.

**Table T-1. Trends in U.S. Per-Capita Consumption of All Dairy Products**

| <b>Year</b> | <b>Pounds, Milk<br/>equivalent, Milkfat<br/>basis</b> | <b>Year</b> | <b>Pounds, Milk<br/>equivalent, Milkfat<br/>basis</b> |

Source: USDA ERS, 2008a; \* Preliminary

The data in table T-1 above includes fluid milk as well as milk used in the manufacture of products such as butter, cheese, yoghurt, ice cream, and powdered milk. The data in the table above indicate a relatively slow annual average growth rate of 0.38 percent in per-capita consumption of all dairy products in the United States. Much of that increase in per-capita consumption seems to have happened in the early to mid 80s.

Milk production grew in the United States from approximately 147.7 billion pounds in 1990 to an estimated 185.6 billion pounds in 2007 (USDA ERS, 2008a). This growth has been relatively continuous and reflects growth in productivity rather than growth in the number of milk cows. The number of milk cows has actually fallen from an average of roughly 10 million in 1990 to less than 9.2 million in 2007 (USDA ERS, 2008a). USDA data on the past 10 years of total milk production and average prices are shown in table T-2.

**Table T-2. Production and Prices for All Milk**

| 2007        | 185.6                               | 19.21                 |

Source: USDA ERS (2008a)

USDA ERS production and price projections through 2017, are shown in table T-3 below. The USDA ERS production forecasts through 2017 above are based on a nearly 1 percent annual average production growth rate. This forecast is consistent with La Due et al (2003), who argue

that the main driver of dairy demand growth in the United States is likely to be overall population growth.

**Table T-3. Projected U.S. Production and Prices for All Milk**

| <b>Year</b> | <b>Production (billions of lbs)</b> | <b>Price (\$/cwt)</b> |
|-------------|-------------------------------------|-----------------------|
| 2008        | 190.1                               | 18.15                 |

California, Wisconsin, New York, Pennsylvania and Minnesota have been the top five dairy producing states in country for over 30 years, although not always in that order and with a growing importance of Western states among the top dairy producers, including Idaho, New Mexico and Washington State (Short, 2004).

### 2.1.2 Meat

Beef production is another important source of demand for alfalfa hay. Table T-4 below provides trend beef consumption data for the US.

**Table T-4. US Domestic Beef Consumption**

| <b>Year</b> | <b>Millions of Pounds</b> |
|-------------|---------------------------|
| 1997        | 25,944                    |
| 1998        | 26,568                    |
| 1999        | 27,172                    |
| 2000        | 27,562                    |
| 2001        | 27,229                    |
| 2002        | 28,080                    |
| 2003        | 27,205                    |
| 2004        | 27,926                    |
| 2005        | 27,919                    |
| 2006        | 28,294                    |
| 2007        | 28,285                    |
| 2008        | 28,281                    |

Source: USDA FAS, 2008.

Total US domestic beef consumption has increased moderately since 1997. Looking back even further, to 1987, the trend annual average growth rate in US domestic beef consumption from 1987 to the current year is about 0.46% a year, or somewhat less than that for all dairy products.

Beef cows represent a much larger portion of total cattle in the US than do milk cows. As of January 2008, there were 96.7 million cattle in the US and just less than ten percent were dairy cows. About 32.6 million were considered beef cows. Only female cattle that have already calved are counted as beef or dairy cows. Male cattle and females who have not calved are not

included. Some of these cattle may be used for beef, but their purposes are not designated by the USDA. There were 54.9 million “other” cattle in the U.S. as of January 2008 (USDA NASS, 2008)

The population growth of beef cows has hovered between -1% and 1% a year for most of the past decade. The overall trend has been slightly negative, registering an average annual growth rate of -0.33% from 1998 to 2008. After a positive spike in 2005 and 2006, beef cow population growth rates have taken a dive in the past two years (-1.21% in 2007 and -0.92% in 2008). Other non-milk cattle have demonstrated a similar long term trend, with a -0.32% average annual growth rate, but with slightly larger ups and downs. These cattle have not, however, seen the same recent population decrease as beef cows have. Growth rates for 2007 and 2008 respectively were 0.46% and -0.18%. The 2008 combined growth rate for all non-dairy cattle was -0.45%, indicating a slight negative population trend at present (USDA NASS, 2008)

Meat production appears to not have been significantly affected so far by the recent decrease in beef cattle. Production has been increasing each year since 2004, but is expected to decrease in 2009 (USDA ERS, 2008a).

**Table T-5. Beef Production**

| Year                         | 2004   | 2005   | 2006   | 2007   | 2008   | 2009   |
|------------------------------|--------|--------|--------|--------|--------|--------|
| <b>Beef (Million Pounds)</b> | 24,548 | 24,683 | 26,153 | 26,421 | 26,827 | 26,385 |
| <b>% Change</b>              | n/a    | 0.55%  | 5.78%  | 1.02%  | 1.52%  | -1.66% |

### 2.1.3 Livestock and Pet Care

Alfalfa hay is also used to feed horses and other domestic equids (domestic equids include horses, ponies, mules, burros, and donkeys). Of the total US equine population in January 1998, 88 percent were horses, 5 percent were ponies, and about 6 percent were mules, donkeys, burros, or miniature horses (USDA APHIS 2008). Table T-6 below provides information on the US on-farm horse inventory.

**Table T-6. On-Farm U.S. Horse and Pony Inventory**

| Year     | Number    |
|----------|-----------|
| 1987     | 2,456,951 |
| 1992     | 2,049,522 |
| 1997 (1) | 2,427,277 |
| 1997 (2) | 3,020,117 |
| 2002     | 3,644,278 |
| 2007     | 4,028,827 |

Source: 1987, 1992, 1997(1): USDA 1997 Census of Agriculture; 1997 (2), 2002: USDA 2002 Agricultural Census, USDA 2007 Census of Agriculture

There is no single consistent source that provides trend U.S. on-farm horse inventory information going back to 1987. While the Census of Agriculture data show little to no horse inventory growth between 1987 and 1997, the USDA 2002 Agricultural Census data shows a consistent increasing growth rate between 1997 and 2007. Moreover, there is no accurate estimate of the current total number of equids in the United States because a count of equids on nonfarm operations does not exist (USDA APHIS 2007).

There are several other categories of livestock and pets that consume alfalfa hay, haylage, meal, or pellets. Table T-7 shows trend US domestic broiler chicken consumption.

**Table T-7. U.S. Domestic Broiler Chicken Consumption**

| <b>Year</b> | <b>Million Pounds</b> |
|-------------|-----------------------|
| 1997        | 22,679                |
| 1998        | 23,151                |
| 1999        | 24,804                |
| 2000        | 25,296                |
| 2001        | 25,481                |
| 2002        | 27,051                |
| 2003        | 27,646                |
| 2004        | 28,836                |
| 2005        | 29,608                |
| 2006        | 30,139                |
| 2007        | 30,036                |
| 2008        | 30,627                |

Source: USDA FAS, 2008.

Domestic broiler chicken consumption is growing at a relatively rapid rate. Looking back even further to 1987, the trend annual average growth rate in broiler chicken consumption is about 3.5 percent. Alfalfa meal and pellets may be included in chicken feed mix, but as there are likely a wide variety of feed substitutes, it is not clear that alfalfa plays as central a role in chicken feed mixes as in hay feed to cattle and horses.

According to Nelson (2008), alfalfa meal and pellets for livestock and pet feed is primarily supplied by mills in Nebraska, Kansas and Ohio. Nelson reports that there is no publicly available dataset on meal and pellet production. She estimates that the alfalfa meal and pellet market totals approximately 110,000 tons. Nelson notes that even if these estimates were off by a factor of 2, these niche markets would represent far less than 1% of total US alfalfa hay production.

Nelson (2008) also argues that the alfalfa nutritional supplement market (for human consumption) is far smaller than the meal and pellet market, and that likewise no publicly available dataset exists. She reports an estimate that the total US alfalfa supplement market could be satisfied with 10 tons of alfalfa hay production, which could be produced on 1-2 acres.

#### *2.1.4 The Organic Segment*

The organic sector is rapidly growing both in the European Union (EU) and the United States (Dimitri and Oberholtzer 2005). Together, consumer purchases in these two regions made up 95 percent of the \$25 billion in estimated world retail sales of organic food products in 2003 (Willer and Geier, 2005). In reporting the results of their annual manufacturer survey, the Organic Trade Association (2007) reports that US organic food sales were estimated to be \$16.67 billion in 2006, up 22% from 2005 (table T-8).

The Organic Trade Association (2007) goes on to note that organic foods have shown consistent annual growth rates of 15% to 21% since 1997, when fairly comprehensive data were first available. Moreover, they report growth rate data based on historical surveys and interviews with long-time participants in the organic foods business in a similar range of nearly 20% annually since 1990. Organic food sales are projected to continue growing at a similar pace through 2010 (table T-8).

**Table T-8. U.S. Organic Food Sales and Sales Growth Forecasts**

| Category of Food | Sales (Millions of \$) |        |        | Annual Sales Growth Rates (%) |           |                             |
|------------------|------------------------|--------|--------|-------------------------------|-----------|-----------------------------|
|                  | 2004                   | 2005   | 2006   | 2004-2005                     | 2005-2006 | Forecasted Annual 2007-2010 |
| Organic Dairy    | 1,731                  | 2,140  | 2,668  | 24                            | 25        | 20                          |
| Organic Meat     | 195                    | 256    | 334    | 31                            | 30        | 27                          |
| All Organic      | 12,460                 | 13,831 | 16,673 | 11                            | 22        | 18                          |

Source: For 2005-2006, Organic Trade Association Manufacturers Survey (2007); For 2004, Organic Trade Association Manufacturers Survey (2006). Data rounded to the nearest integer value.

Of total 2006 organic food sales reported by the Organic Trade Association (2007), 16% were made up of organic dairy products, while another 2% came from organic meat. Moreover, organic dairy product sales in 2006 were reported to represent an increase of 25% over 2005 levels (table T-8). Table T-8 also provides recent trend sales data for organic meat, indicating an even faster growth rate than organic dairy products, though from a much lower base sales level. The Organic Trade Association (2007) notes that overall consumer purchases of organic foods in 2006 represented only 2.79% of total U.S. food sales, though this figure is up from 0.81% in 1997. The Organic Trade Association (2008) reports that while organic dairy sales in the United States represented 0.79% of all dairy sales in 1997, by 2006 that figure had increased to 4% of all dairy sales.

Organic production may be somewhat lagging the growth in demand – the Organic Trade Association (2006) indicated that 52% of respondent firms reported that a lack of dependable supply of organic raw materials has restricted their company from generating more sales of organic products. Willer et al 2008 report that organic agricultural land represented 0.5 percent of all agricultural land in the US in 2006, somewhat below the worldwide average.

There is evidence that perceptions of higher organic food safety may be an important driver for consumer substitution of organic for conventionally produced food. In particular, Dimitri and Oberholtzer (2005) argue that changes in organic and conventional food demand are driven in part by “food scares.” They note, for example, that mad cow disease (Bovine Spongiform Encephalopathy - BSE) was considerably affected to the European organic livestock and dairy industry. Dimitri and Oberholtzer (2005) report that in response to news reports on BSE, many consumers substituted organic dairy and meat products (which European consumers perceived as safer) for conventionally raised dairy and meat products. For example, they report that organic food sales in Germany increased by 30 percent in 2001 as a result of BSE.

Moreover, Dimitri and Oberholtzer (2005) report that other food scares that caused European consumers to substitute organic for conventionally produced food include episodes of contaminated chicken feed in Belgium in 1999, feed contaminated by dioxin in 2004, and more

recently, carcinogenic food dyes in TV dinners in Ireland in 2005. It is interesting to note, however, that Dimitri and Oberholtzer (2005) do not find evidence that U.S. consumers are as strongly affected by food scares.

## 2.2 Consumer Sensitivity to Genetically Engineered Content in Food

Most U.S. consumers are unaware of the prevalence of GE products in the US food supply (Anderson et al. 2006; Hallman and Hebden 2005; Thomson and Dininni 2005). Hallman et al. (2003) found that only one-fourth of US residents believed that they had ever consumed food containing GE ingredients. There seems to be no estimate available of consumer demand for GE-free food products (Noussair et al, 2004).

However, in the last decade, there has been a considerable number of attempts to identify consumer preferences regarding GE foods, in and outside the United States, most of them based on consumer surveys, done under various conditions, asking consumers to express their preferences under hypothetical situations. The results overwhelmingly show lack of information regarding GE foods and considerable resistance towards their consumption (Hallman and Aquino, 2003).

For example, various Eurobarometer<sup>77</sup> surveys have reported that most Europeans are not able to correctly answer whether the phrase “ordinary tomatoes do not contain genes, while genetically modified tomatoes do” is true or false (Rigby et al, 2004). Anderson et al. (2006) argue that while the specifics differ, in general the literature indicates that US consumers have relatively little knowledge of biotechnology.

Many contingent valuation studies exist for Europe, United States, Japan and Australia reporting that consumers are typically willing to pay a higher price for GE-free foods, and various articles review this literature (Lusk et al, 2004; Rigby et al, 2004).

Contingent valuation studies and surveys based on hypothetical situations are known to be very poor predictors of actual behavior in the market (Noussair et al, 2004; Fernandez-Cornejo and Caswell, 2006). To address this deficiency, a number of studies have implemented experiments, in which consumers actually get to choose among products and benefit from their choices. Lusk et al (2004) develop a meta-analysis of 25 studies including 57 valuations of GE foods. Most of the studies analyzed are for the United States, a third is for Europe and other studies include Asia, Canada and Australia. Seventeen of the studies are based on consumer surveys while eight are based on experiments. They find that the willingness to pay for GE-free foods was lower in experimental studies, although still positive.

A number of other studies have investigated whether the resistance to GE foods and the lack of information regarding biotechnology are correlated. Chern and Rickertsen (2002) conducted a student survey in four countries (United States, Japan, Norway and Taiwan) and a national phone survey in the United States and Norway. Willingness to consume GE foods increased when it was explained that GE foods could include benefits such as the reduced use of pesticides.

---

<sup>77</sup> Surveys conducted on a regular basis for the European Commission, executive branch of the European Union

Bertolini et al (2003) compared attitudes towards GM foods in the US, Japan and Italy in random surveys of food shoppers. They also found a positive impact of familiarity with GE products on acceptance. On the other hand, Hallman and Aquino (2003) conducted a survey of a random sample of US households and found out that improved information on GE foods did not necessarily mean increased approval. Those most knowledgeable about genetic engineering tended to have more extreme opinions, in favor or against, than those less knowledgeable. Noussair et al (2004) also found that prior beliefs regarding GE foods had a stronger influence on consumer choice than information.

Studies also exist investigating how consumers value varying levels of content of GE products in their foods. In an experiment in France, where consumer surveys reveal very strong resistance to GE products, Noussair et al (2004) found that 89% of consumers were willing to purchase a product with up to 1% GE content and 96% with up to 0.1% GE content. They also found that consumers differentiated between GE-free and 0.1% of GE content. Rigby et al (2004), on the other hand, in a nationwide study of the United Kingdom found that consumers did not distinguish between 0% and 0.5% GE levels and did not place a value in having products with 0% GE content as opposed to 0.5%.

In response to consumer concerns, over forty countries have adopted labeling regulations for GE products (Guère et al, 2007)<sup>78</sup>. In Europe, the main impact of labeling requirements has been the virtual disappearance of many GE products, given that the cost differentials in production are small (since often GE ingredients are a minor share of total ingredients in products) and the risk of loss of market share is high given the perceived consumer resistance (Guère et al, 2007). In addition, to the extent that labeling requirements require segregation of GE and non-GE products throughout the production process, labeling may imply considerable costs (Noussair et al, 2004).

### *2.2.1 United States*

There is relatively little literature specifically assessing purchase motivations associated with genetically engineered foods in the United States, which Anderson et al. (2006) attribute in part to the current lack of genetically engineered content labeling. In their summary of 25 valuation studies relating to GE food, Lusk et al. (2005) found that U.S. consumers are more receptive to GE foods than their European counterparts, although a preference for non-GE foods remains, suggested by various estimates of willingness to pay for GE-free foods.

Lusk and Rozan (2005) attribute differences in GE product receptivity by consumers in France and the United States, partially to differences in information about GE foods and partially to different levels of trust in the sources providing information. While the United States showed greater knowledge of GE foods, there was also greater trust in the institutions delivering the information (food regulatory agencies, universities, agribusiness). Rigby et al (2004) find similar results for the United Kingdom as Lusk and Rozan (2005) find for France regarding the lack of trust of consumers towards institutions concerning information about GE products. The only institutions that more than 10% of consumers were willing to trust for information were universities/educational organizations.

---

<sup>78</sup> Some of these regulations have not yet been implemented or only partially so.

There is some evidence that consumers support genetic engineering for use in crops to a greater extent than in animals from which dairy, meat, and other food products derive (Ganiere et al. 2006). Hallman et al. (2003) reported that one-half of US residents surveyed approved of plant-based genetic engineering, while only one-quarter approved of it for use in animal agriculture.

Lusk et al. (2003) developed a mail survey sent to consumers in France, Germany, the United Kingdom, and the United States concerning preferences relating to the use of growth hormones and GE corn feed in cattle from which ribeye steaks were produced. The survey contained a choice experiment in which consumers made choices between ribeye steaks with varying levels of price, marbling (intramuscular fat), tenderness, and use/ non-use of growth hormones and genetically engineered corn in livestock production. Lusk et al. (2003) found that European consumers were more concerned about the use of genetic engineering and biotechnology than consumers in the United States. On a scale of 1 (not at all concerned) to 5 (very concerned), Lusk et al. (2003) found that consumers in France, Germany, and the United Kingdom reported average levels of concern of 4.73, 4.53, and 4.24, whereas the average US level of concern was 4.00. They also found that US consumers are more averse to hormone use than use of GE animal feed.

Fernandez-Cornejo and Caswell (2006) argue that there are many products in the United States that contain GE ingredients, and that the demand for these products apparently has been unaffected by negative opinions about biotechnology expressed in surveys. Putnam (2005) makes this same point, arguing that GE crops such as corn and soybeans have been used as animal feed for years with no perceptible impact on the marketing of beef. He observes beef consumers are more concerned with hormones and antibiotics or diseases such as Mad Cow disease.

The evidence so far suggests that although US consumers prefer to avoid GE foods, they are less concerned than their European counterparts. Other GE crops (e.g., corn, soybeans, canola) have been deregulated in the US for a number of years with no substantial drop in demand for conventionally produced dairy products or meat.

In the case of organic foods, one of the unique attributes of organic foods, and one reason consumer demand for organic foods is increasing, is the intended absence of GE ingredients in the process of producing them (Anderson et al. 2006; Dhar and Foltz 2005; Larue et al. 2004).

The USDA National Organic Program (NOP) standards currently require that goods labeled “100% organic” must be produced and handled without the use of excluded methods, one of which is the form of genetic engineering used to produce GT alfalfa cultivars. Livestock standards applied to animals used for meat, milk, eggs, and other animal products call for animals to be fed 100% organic feed, with vitamin and mineral supplements excepted (USDA NOP 2008). At the present time, however, there is no policy regarding the unintended presence of GE material in organic products or food, consistent with the fact that the NOP is process-based, not product-based. By way of comparison, the NOP has a content threshold for synthetic pesticide residues equal to 5% of the EPA’s specific tolerance level for each type of pesticide residue detected (Ronald and Fouche 2006).

## 2.3 Discussion

The evidence above suggests a preference for GE-free foods among some U.S. consumers is often detected in consumer surveys. However, there is little evidence that this stated preference translates into decreased demand for conventional foods.

There is some debate on whether the absence of mandatory labeling for GE foods in the U.S. leaves the consumer less informed about the available choices than the current system of voluntary labeling with various authors suggesting this is not the case (Bansal and Ramaswami, 2007; Huffman et al, 2002).

Some suggest, however, that preference for GE-free foods may be correlated with the growth of organic foods. Anderson et al. (2006) argue that along with ethical considerations, the potential motivators for GE-free foods will likely mirror those of the organic industry, linking acceptance to perceptions of the benefits and risks associated with human health, safety, ethics, and the environment (Larue et al. 2004; Onyango and Nayga 2004). Much of the information that US consumers currently have regarding purposeful GE content in the foods they eat comes from the presence or absence of organic labels (Ganiere et al. 2006). There is some evidence that attitudes about organic foods can be a useful indicator of attitudes about foods with GE content, at least outside of the United States (Burton et al. 2001).

There is some evidence of higher levels of consumer confidence in organic foods, particularly in comparison to conventionally produced foods made in the absence of restrictions or content labels indicating GE content (e.g., Anderson et al. 2006; Owen et al. 2005). In the context of deregulating GT alfalfa as livestock feed, there is thus the potential for an additional increase in demand for organic foods as a substitute for conventional foods.

Successful marketing of NOP certified foods has already had to contend with the risk of GE material accidentally spreading from deregulated cultivars of soybeans, corn, and canola to organic crops. Despite the potential for unintended presence of GE material, however, the evidence cited above indicate that organic food sales in the United States continue to grow at a rapid rate.

As noted earlier, one reason may be that most US consumers do not appear to have strong or well-formed adverse opinions regarding health or safety impacts from GE foods deregulated for US production. Another is that ethical and environmental factors largely unrelated to unintended presence of GE material are important drivers of organic demand (Anderson et al. 2006). While there is the potential that organic food sales would have grown even more rapidly in the absence of this risk, no published studies have been found that document or estimate this effect.

Will organic food sales continue to grow at current trend rates in the context of the deregulation of GT alfalfa? In the absence of published studies documenting prior adverse impacts on organic food demand from previously deregulated genetically engineered crop cultivars, we cannot conclude that this will or will not occur.

One niche sector that may potentially benefit from consumer concerns regarding unintended presence of GE material is farmers' markets, to the extent that they serve as an outlet for dairy and meat products. However, most states regulate or prohibit the sale of fresh meat and milk due to food safety concerns at Farmers' Markets ([http://www.ksda.gov/food\\_safety/content/318](http://www.ksda.gov/food_safety/content/318), <http://www.vermontagriculture.com/agdev/documents/farmersMarketRegulations.pdf>, <http://www.agr.state.ne.us/pub/daf/farmmkt.htm>, <http://www.cga.ct.gov/2006/ACT/PA/2006PA-00052-R00SB-00294-PA.htm>, <http://www.portlandmaine.gov/voter/farmerrules.pdf>, [http://www.ccdeh.com/commtee/food/documents/Guidelines/Certified\\_Farmers\\_Markets.pdf](http://www.ccdeh.com/commtee/food/documents/Guidelines/Certified_Farmers_Markets.pdf)). Kremen et al. (2004) find, for example, many customers at farmers' markets value having direct access to farmers that use ecologically sensitive agricultural techniques—such as organic production methods—on their farms. The trust relationships and repeated direct interaction between local small-scale farmers and consumers at farmers' markets may serve as an alternative to conventional grocery store purchases in the context of concerns about the presence of GE material in foods. As organic farmers make disproportionately high use of farmers' markets as sales outlets (Kremen et al. 2004), again it isn't clear that the overall organic food sector will suffer a decline in demand.

Taken as a whole, there is no evidence to suggest that deregulation of GT alfalfa will reduce demand for organic foods. The evidence presented in section 2.2 suggests that the deregulation of GT alfalfa may in fact increase demand for organic foods.

## 2.4 Summary of Findings

There is evidence of moderate overall growth in key downstream markets for alfalfa. There is also evidence of some consumer preference for GE-free foods in the United States. Growth trends in downstream markets, however, occurred in the context of the US deregulation of other GE feed crops such as corn and soybeans. There is no evidence on whether these trends would have been higher or lower in the absence of GE feed.

Consumer preference for GE-free foods may have contributed to strong growth in the organic sector. There is no evidence to suggest that deregulation of GT alfalfa will reduce demand for organic foods. The evidence presented indicates that consumer preferences for organic over GE foods are influenced in part by ethical and environmental factors that are likely unrelated to minor unintended presence of GE material in feed crops. Moreover, there is no evidence that any GE material (either the transgenic DNA or the transgenic protein) in animal feed currently in use is actually transmitted to milk or meat (Phipps et al. 2006), and there is no evidence that the GT trait in alfalfa has an effect on the composition of the milk (Combs and Hartnell, 2007). Therefore, no tests can be conducted on the milk or meat to confirm the presence or absence of GE material. The demand for organic foods has steadily grown at double-digit rates throughout the period of time in which other GE animal feeds have been deregulated for use in the US. The evidence presented above suggests that there is actually the possibility that deregulation of GT alfalfa may in fact increase demand for organic foods as consumers concerned with GE foods may switch to organic products, in the absence of GE labeling.

## 3.0 Impacts of Changes in Production Costs

### 3.1 The Role of Alfalfa Feed Costs in Downstream Production

#### 3.1.1 Dairy

USDA estimated production costs for dairy farms in the United States based on the 2005 Agricultural Resources Management Survey (ARMS). According to these data, feed corresponds to 30%-60% of total production costs per hundredweight (100 pounds) sold. The weight of feed on total costs is larger for smaller farms given the lower productivity and relatively larger overheads. As farmers may choose to attribute overhead costs to other farm products or abdicate from covering them for short periods of time, it is relevant to also look at the share feed costs represent on operational costs: roughly 70-85%. This suggests the price of feed is a major determinant of the cost of dairy production for dairy farms.

**Table T-9. Weight of Feed Costs in Dairy Farms**

| <b>Farm Type</b>               | <b>Feed costs/ Operational costs</b> | <b>Feed costs/ Total costs</b> |
|--------------------------------|--------------------------------------|--------------------------------|
| Conventional U.S.              | 73.3%                                | 44.1%                          |
| Conventional California        | 79.7%                                | 57.8%                          |
| Conventional Wisconsin         | 72.0%                                | 40.4%                          |
| Conventional <50 cows          | 73.4%                                | 30.0%                          |
| Conventional 1000 cows or more | 83.3%                                | 44.1%                          |
| Organic U.S.                   | 77.8%                                | 41.9%                          |
| Organic <50 cows               | 76.9%                                | 33.7%                          |
| Organic 200 cows or more       | 79.6%                                | 42.8%                          |

Source: USDA ERS, 2005

Alfalfa is likely a considerable share of feed costs. Short (2004) reports hay and straw, presumably mostly alfalfa, representing roughly a third of feed costs. Alfalfa may additionally be used in cubes or pellets. In some regions (Wisconsin, Minnesota) haylage is also a significant share of feed.

In our Technical Report *Changes in the Economics of Alfalfa Farming with the Deregulation of Glyphosate-Tolerant Alfalfa* (appendix K) we argued that adoption of GT alfalfa is likely to increase the quality of alfalfa for forage without an increase in costs. This should increase productivity of dairy farms and allow for an increase in production without an increase in costs. We argued that this would correspond to a shift downwards (increased production at lower prices) in the supply curve of alfalfa for forage.

The impact on dairy farms will be to increase the feasibility of operations. MacDonald et al (2007) report that currently many small dairy farms are operating with incomes above operational costs but below total costs (they are not covering overhead and capital recovery costs). The impact on reduced costs will, however, impact farms of all sizes, since feed seems to be of similar importance to all farms. If GT alfalfa requires less household labor, this may come to the advantage of smaller farms where household labor is a greater share of costs.

Whether decreased dairy farm production costs and a potential increase in production will reflect in reduced prices for dairy is not clear. A report by the United States General Accounting Office (2001) studied the factors influencing farm and retail dairy prices. The report notes that changes

in milk production costs do not necessarily reflect in changes in retail prices of dairy. Farmer milk prices represent roughly 40% of retail milk prices and are affected by Federal and State programs establishing minimum prices. The process of transmission of dairy farms costs to prices is not a simple one to determine.

### *3.1.2 Meat*

USDA ERS produces cost estimates annually for a variety of farm products. According to the latest estimates (2005-2006), feed corresponds to an average of 56.8% of operational costs and 28.8% of total costs of cow-calf production (USDA ERS, updated 2008). Harvested forages correspond to almost half of feed costs (46.9%). Short (2001) reports somewhat lower figures: 35% of operational costs and 20.8% of operational and ownership costs (capital recovery, taxes insurance) are attributes to feed and only between 10-20% of feed costs would correspond to purchased harvested forages.

Alfalfa is likely a lower share of feed costs in cow-calf production than it is in dairy production since the main source of feed is grazing (Short, 2001). As cattle move on to feedlots (sometime through stocker operators) feed becomes mostly grain based ration.

The impact of potentially reduced alfalfa costs on meat production may be important for cow-calf production, particularly in areas where supplementary feeding is more important in winter, such as the North Central region – Iowa, Illinois, Missouri (Short, 2001). If the alfalfa used is often of lower quality (Klonsky et al, 2007) this impact would depend on the extent to which reduction in prices of high quality alfalfa also brings down that of lower quality alfalfa.

Short (2001) argues that prices paid for cattle tend to be similar across the country, despite differences in cow-calf production costs because cattle are routinely transported. This suggests that any transfer of cost changes to prices down the chain is unlikely.

### *3.1.3 Livestock and Pet Care*

Of the remaining potential sources of demand for alfalfa hay, the most important is likely horses. Putnam (2005) estimates that horses may consume between 5%-15% of alfalfa hay in California. He also, however, describes the horse market for alfalfa hay as idiosyncratic, subjective, and supplied by alternative hay such as timothy and grass. We have not found sufficient reliable information – budgets and potential substitutability within horse feed – to generate an informed analysis of the impact of GT alfalfa deregulation on the horse market.

## **3.2 Substitution Effects**

One reason why the extent to which potentially reduced alfalfa costs affect downstream market prices is important, is that it may cause substitution of products produced with lower cost/higher quality alfalfa for product produced with higher cost/ lower quality alfalfa. As an example, if lower GT alfalfa costs translated into lower conventional dairy prices, the price differential between organic dairy products and conventional dairy products would increase, reducing the

number of consumers willing to pay higher prices for organic dairy. This would trickle back to organic alfalfa farmers that would face reduced demand for organic alfalfa.

In the case of dairy products there may be a shift towards the use of GT alfalfa as forage and a shift towards higher quality alfalfa hay, as argued in our Technical Report *Economic and Social Impacts to Conventional and Organic Farmers of Deregulation of Glyphosate-Tolerant Alfalfa* (appendix S). To the extent that alfalfa and other forms of feed are substitutes, there may also be some shift towards alfalfa based feed. However, beyond the farm gate, we are unable to tell whether there will be any transmission of lower costs to dairy prices. As previously explained, the establishment of milk prices is regulated by federal and state programs and its response to shifts in costs, as well as to changes in supply and demand is not clear.

To the extent that any increases in milk production are allowed by decreased feed costs, and to the extent that dairy prices response to shifts in milk production, there could presumably be some pressure downwards in dairy retail prices. However, as previously noted, dairy retail prices suffer a greater influence from other factors.

In the case of meat, we found little reason to believe changes in costs will be transmitted down the production chain such as to significantly impact meat prices.

Impacts of decreased costs of alfalfa on downstream markets for livestock and pet care will likely not significantly reflect back on the demand for alfalfa hay, given the minor share of these downstream markets in overall demand for alfalfa.

### 3.3 Summary of Findings

Expected lower prices/ higher quality of alfalfa hay will likely benefit dairy farmers and to a lesser degree cow-calf production.

The reduced costs in dairy and meat farming may not be transmitted to dairy and meat products. In the case of dairy, this is because of dairy price regulation. In the case of meat, this is because of the relatively low weight of alfalfa in total costs. The result is that price differentials between organic and conventional dairy and meat products may not be affected by the increased supply of high quality alfalfa hay expected with GT alfalfa deregulation.

## **Appendix T-2. Literature Search**

### **1.0 Literature Search Strategy**

For data on downstream markets we searched mostly USDA sources.

For the literature on GE sensitivity of demand, the search started with general internet searches and then snowballed from references found in various papers. Most of the references come from academic journals and conferences.

Cost studies for dairy and meat production were found with USDA's Economic Research Service using information from the Agricultural Resources Management Surveys.

## **Appendix U: Character and Quality of Glyphosate-Tolerant Alfalfa Traits**

# Character and Quality of Glyphosate-Tolerant Alfalfa Traits

## 1.0 Introduction

Monsanto Company and Forage Genetics International (FGI) have developed varieties of Roundup Ready<sup>®</sup> alfalfa using *Agrobacterium*-mediated transformation to stably incorporate into the alfalfa genome a coding sequence that produces a glyphosate-tolerant (GT) form of the enzyme 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS). The production of the CP4 EPSPS protein in plant tissues is the basis of the Roundup Ready, glyphosate-tolerant trait in alfalfa varieties. GT alfalfa is tolerant to foliar applications of glyphosate allowing for post emergent control of most weeds in alfalfa fields. The methodology for plant transformation and subsequent product characterization data are described in detail in Petition Number 04-110-01p ([http://www.aphis.usda.gov/brs/aphisdocs/04\\_11001p.pdf](http://www.aphis.usda.gov/brs/aphisdocs/04_11001p.pdf)). GT alfalfa varieties have been commercialized using a combination of the two different *cp4 epsps* insertion events (J101 and J163) combined through a conventional breeding process.

### 1.1 Weed Potential (Phenotypic Assessment)

Monsanto and FGI have performed a characterization of GT alfalfa populations containing events J101 and J163. Information was developed to assess whether the trait, the transformation process, or ensuing tissue culture process produced alfalfa events that would impact the plant pest characteristics of alfalfa differently than those observed for the control or conventional alfalfa varieties. Phenotypic, agronomic and compositional information also were provided to assess whether other plant characteristics were affected by the transformation as a means to detect if any unintended effects may be involved. For alfalfa, characteristics that may impact plant pest risk include enhanced growth, vigor or stand longevity; changes in susceptibility to plant pests and diseases; increases in seed yield; and changes in seed dormancy. The overall conclusions from the characterization were that there are no biologically meaningful differences between alfalfa populations that contain event J101 or J163 and the nontransformed alfalfa control or alfalfa reference variety populations (USDA EA for petition 04-110-01p, [http://www.aphis.usda.gov/brs/aphisdocs2/04\\_11001p\\_com.pdf](http://www.aphis.usda.gov/brs/aphisdocs2/04_11001p_com.pdf)). Crop compositional data and other phenotypic and agronomic data also led to the conclusion that alfalfa populations containing event J101 or J163 were not different from the nontransformed control or conventional alfalfa populations (USDA EA for petition 04-110-01p, [http://www.aphis.usda.gov/brs/aphisdocs2/04\\_11001p\\_com.pdf](http://www.aphis.usda.gov/brs/aphisdocs2/04_11001p_com.pdf)). The phenotypic evaluation was based on both laboratory experiments and replicated, multi-site field trials conducted over five years (1999-2003) by agronomists and scientists who are familiar with the production and evaluation of alfalfa. In each of these assessments, event J101 and event J163 were compared to an appropriate alfalfa control. Detailed information may be found in section VI of Petition Number 04-110-01p. As a result of this assessment, it was concluded that there were no

meaningful changes in the phenotype of J101 and J163 and no increased pest potential (USDA EA for petition 04-110-01p, [http://www.aphis.usda.gov/brs/aphisdocs2/04\\_11001p\\_com.pdf](http://www.aphis.usda.gov/brs/aphisdocs2/04_11001p_com.pdf)). Broad data categories evaluated as part of the phenotypic and familiarity assessment are presented in table 1. The vast majority of this information was previously submitted to USDA in Petition Number 04-110-01p. A summary of the characterization data developed to support the food, feed and environmental safety assessment as well as additional relevant information developed after deregulation is provided in the following sections.

**Table U-1. Data Categories Evaluated for Assessment of Weed Potential and Familiarity of Glyphosate-Tolerant Alfalfa**

|                              |                                                                                                                                                                                                                                                                                                                                                                                                        |
|------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Phenotype/agronomic          | Comparative information on the growth and development characteristics listed below was collected on test or control alfalfa populations to determine whether the trait or transformation process altered alfalfa's weed potential. Except where noted, data were collected from alfalfa established at four locations over three seasons using a randomized complete block design with four replicates |
| Seedling emergence           | Number of emerged seedlings two to three weeks after establishment. (Faster seedling emergence may result in greater weediness potential)                                                                                                                                                                                                                                                              |
| Seedling vigor               | Evaluation of seedling vigor three to four weeks after establishment. (Greater seedling vigor may result in greater weediness potential)                                                                                                                                                                                                                                                               |
| Spring vigor                 | Evaluation of spring re-growth in the second and third season at the 4-6 inch stage. (Higher spring vigor may result in greater weediness potential)                                                                                                                                                                                                                                                   |
| Spring stand                 | Determination of the percentage of plants surviving winter at the beginning of the second and third season. (Better spring stand may result in greater weediness potential)                                                                                                                                                                                                                            |
| Forage/seed yield            | Forage yield taken at approximately 4-6 week intervals throughout the season. Seed yield taken from greenhouse and field grown plants. (Higher forage yield (faster growing plant) and higher seed yield (more and or larger seeds) may result in greater weediness potential)                                                                                                                         |
| Crop growth at cutting       | For selected cuttings, crop growth stage was determined using the Mean Stage by Count (MSC) method (Kalu and Fick, 1981). (Changes in plant growth and structure may result in greater weediness potential)                                                                                                                                                                                            |
| Regrowth after cutting       | Regrowth at 10 to 15 days after each cutting in the second and third season. (Faster regrowth may result in greater weediness potential)                                                                                                                                                                                                                                                               |
| Fall plant height            | Fall plant height measurements taken in the second and third seasons as an indicator of fall dormancy. (Changes in fall plant height may result in greater weediness potential)                                                                                                                                                                                                                        |
| Fall growth habit            | Categorical score of selected plants for fall growth habit as upright, prostrate, or a mixture of both types. (Changes in fall growth habit may result in greater weediness potential)                                                                                                                                                                                                                 |
| Biotic and abiotic stressors | Observation of alfalfa response to insects, diseases, weeds and abiotic stressors during growing season. (Greater tolerance to stressors may result in greater weediness potential)                                                                                                                                                                                                                    |
| Reproductive characteristics | Assessment of flower morphology, pollen morphology, and pollen viability in greenhouse grown plants. (Changes in reproductive characteristics may result in greater weediness potential)                                                                                                                                                                                                               |
| Stand longevity              | Census of plants remaining in the stand taken at the end of each season (three seasons, one location). (Greater stand longevity may result in greater weediness potential)                                                                                                                                                                                                                             |
| Allelopathy                  | Evaluation of allelopathic potential of alfalfa through laboratory analyses of plant root exudates and field observations of rotational crop growth and development. (Higher level of allelopathy may result in greater weediness potential)                                                                                                                                                           |
| Crop composition             | Compositional evaluation of forage as a measure of lack of unintended effects (McCann, et al., 2006; Steckel and Hayes., 2006))                                                                                                                                                                                                                                                                        |
| Dormancy/germination         | Germination and dormancy potential measured over multiple temperatures using seed industry standard testing methods (AOSCA, 2003). (Faster germination and changes in seed dormancy may result in greater weediness potential)                                                                                                                                                                         |
| Gene flow                    | Determination of amount of gene flow using <i>cp4 epsps</i> as a marker (Fitzpatrick, et al., 2003)                                                                                                                                                                                                                                                                                                    |
| Plant biogeography           | Census of feral alfalfa populations present in six U.S. alfalfa producing states (Kendrick, et al., 2005)                                                                                                                                                                                                                                                                                              |
| Symbiotic organisms          | Measurement of nodule numbers and morphology in greenhouse and field grown plants to assess symbiotic relationship between <i>M. sativa</i> and <i>Sinorhizobium meliloti</i>                                                                                                                                                                                                                          |

## 2.0 Crop Compositional Assessment

Crop compositional data were reviewed and analyzed by USDA APHIS as part of the familiarity assessment and to confirm that there were no unintended effects. These data also were provided to the FDA to confirm food and feed safety comparable to conventional alfalfa varieties. A brief summary of the information reviewed by USDA and FDA follows. GT Alfalfa varieties were grown at five replicated field sites across the alfalfa-producing regions of the U.S. during the 2001 field season. Field sites were located in the states of California, Illinois, New York, Washington and Wisconsin. Plots containing GT alfalfa lines were treated with a Roundup agricultural herbicide at 1.5 lbs a.e./acre/application. Multiple applications were made to each field site (up to 7.5 lb a.e./acre). Forage samples were collected from all plots and analyzed for nutritional components. Compositional analyses of the forage samples included proximates (protein, fat, ash and moisture), acid detergent fiber (ADF), neutral detergent fiber (NDF), lignin, amino acids, and minerals (calcium, copper, iron, magnesium, manganese, phosphorous, potassium, sodium and zinc), as well as carbohydrates by calculation. In all, 35 different components were analyzed to assess the composition of GT alfalfa.

Components measured are consistent with those suggested by the OECD consensus document (OECD, 2005). To confirm the nutritional equivalence and evaluate whether the trait or transformation process had any unintended effects on alfalfa, the following components were measured: proximates (moisture, protein, fat and ash; carbohydrates), concentration of individual amino acids, ADF, NDF, lignin, and minerals (calcium, copper, iron, magnesium, manganese, phosphorus, potassium, sodium and zinc). Components were selected after consideration of the role alfalfa plays as a source of nutrients in the diet and on the basis of what animal nutritionists consider is important from a feeding value perspective. Protein, ADF, NDF, fat, ash and lignin are used to determine the feeding value of alfalfa. Lignin is also usually the major factor limiting digestion of cell walls which in-turn impacts digestibility. High concentrations of lignin may reduce digestibility and can be an anti-quality factor. The feeding value of alfalfa exceeds that of other perennial grasses primarily because alfalfa has higher intake potential associated with faster digestibility. Minerals present in alfalfa can contribute significantly to meeting the mineral requirements of animals. The mineral content of alfalfa is taken into account by livestock nutritionists when formulating diets to meet or exceed National Research Council guidelines for maintenance, growth and lactation. Measurement of individual amino acids was included because CP4 EPSPS is involved with the synthesis of aromatic amino acids, which are important as a source of protein in alfalfa animal feed.

Statistical evaluation of the composition data involved comparison of the forage from the alfalfa test lines to the nontransgenic control. Statistically significant differences were determined at the 5% level of significance ( $P \leq 0.05$ ). Compositional data on forage derived from the GT alfalfa plants containing event J101, J163, or the confirmatory synthetic population, J101XJ163, were reviewed and analyzed by USDA APHIS (data found in section VI, subsection H of Petition Number 04-110-01p). It was concluded that forage derived from J101 and J163 was compositionally equivalent to forage produced by conventional alfalfa (USDA EA for petition 04-110-01p [http://www.aphis.usda.gov/brs/aphisdocs2/04\\_11001p\\_com.pdf](http://www.aphis.usda.gov/brs/aphisdocs2/04_11001p_com.pdf)).

Additional compositional analyses conducted after deregulation of GT alfalfa support these same conclusions. McCann et al (2006) summarized compositional data derived from GT alfalfa harvested in the establishment year and in the third year of the stand. These data are the same as those reported in Petition Number 04-110-01p. Forage analyses of samples collected from the third year included coumestrol, an important phytoestrogen. In this study, GT alfalfa had been treated multiple times with Roundup Agricultural herbicide at 1.5 lbs a.e./acre with cumulative doses of up to 7.5 and 16.5 lbs a.e./acre for the 2001 and 2003 growing seasons, respectively. It was concluded that forage derived from the 2001 and 2003 plots was compositionally equivalent to that derived from the control and conventional alfalfa plots, thus confirming compositional equivalence between GT alfalfa and conventional alfalfa forage. Furthermore, cumulative glyphosate treatments had no effect on the quality of forage harvested from GT alfalfa. Similarly, Steckel and Hayes (2007) concluded that forage quality and yield were unchanged over a three year period where GT alfalfa was treated numerous times at various single application rates (0.75 to 3 lbs a.e./acre) with a cumulative dose of 9 lbs a.e./acre.

### **3.0 Nutrient/Water Uptake**

Agriculture is a major user of ground and surface water in the United States, accounting for over 80 percent of fresh water in the U.S. and exceeding 90% in some western states, which is the major area for irrigated agriculture (USDA-ERS, 2007). Where agricultural lands are irrigated, alfalfa is one of the crops contributing to the use of water. As noted in the EA (USDA EA for petition 04-110-01p [http://www.aphis.usda.gov/brs/aphisdocs2/04\\_11001p\\_com.pdf](http://www.aphis.usda.gov/brs/aphisdocs2/04_11001p_com.pdf)) and the petition, there are no phenotypic or compositional changes in GT alfalfa; therefore, it is expected that the impact on water use due to cultivation of GT alfalfa would be no different than the water used in cultivating conventional alfalfa. In the petition, data were not developed to specifically address water uptake.

Compositional data included the measurement of micronutrients in forage and, with the exception of iron, there were no biologically meaningful differences between GT alfalfa and control or conventional alfalfa. See section VI, subsection H of Petition Number 04-110-01p and McCann et al. (2006). According to McCann et al. (2006), the increase levels of iron were not associated with nutrient uptake because they were concluded to be due to environmental contamination. Previous reports on the yellow flash in soybean (Gordon, 2005; Ebelhar et al., 2005) suggest that application of glyphosate to GT soybean may effect manganese uptake or metabolism in soils with low levels of manganese, that are on bottomlands, are sandy, or that have high pH levels (pH 6.5 or greater). GT alfalfa varieties were not specifically tested under these conditions; however, levels of manganese were measured in forage and were not significantly different from the control. Since soybean and alfalfa are both legumes, an assumption can be made that yellow flash may occur in alfalfa under special circumstances; but as with soybean, this condition can be expected to not be considered serious with alfalfa.

Alfalfa is a plant that provides nitrogen to the soil due to a *Rhizobium*-legume symbiotic relationship, and high rates of nitrogen fixation are typically observed in alfalfa (Vance et al., 1988). Information reviewed and analyzed by USDA APHIS found in Petition Number 04-110-

01p (section VI, subsection I) showed that there were no differences in the number of nodules or gross morphology of nodules associated with GT alfalfa compared to control alfalfa. Furthermore, when glyphosate agricultural herbicides were applied to GT alfalfa, no differences in nitrogen fixation indicators including total protein levels, amino acids asparagine and aspartate, and forage yield, were observed in GT alfalfa compared to control. Thus, it is not expected that cultivation of GT alfalfa with subsequent applications of glyphosate will impact nitrogen fixation and subsequent nitrogen credits. In soybean, a temporary decrease in the level of *Rhizobia* has been noted after glyphosate application (King et al. 2001, USDA EA GT soybean). Since soybean and alfalfa are both legumes, an assumption can be made that a temporary decrease in *Rhizobia* may occur in alfalfa under special circumstances, but as with soybean, this condition can be expected to not be considered serious with alfalfa.

### 3.1 Disease and Pest Susceptibility

During confined release field trials and after commercialization of GT alfalfa in 2005, GT alfalfa was grown and tested at a broad geographic distribution of sites in the U.S. exposing the varieties to a wide range of naturally occurring diseases and disease complexes. The major diseases of economic importance in the U.S. are those alfalfa pathogens that impact the foliar, crown, root, vascular and seedling health of alfalfa plants. The majority of alfalfa diseases are caused by fungi. However, nematodes, bacteria, viruses and other microbes also incite economic losses in alfalfa production (Leath et al. 1988). The major economic diseases that occurred in the test locations included, but were not limited to: seedling damping-off (e.g., fungal genera such as *Pythium*, *Phytophthora*, *Aphanomyces*); foliar diseases (e.g., fungal genera such as *Leptosphaerulina*, *Colletotrichum*, *Peronospora*, *Phoma*, *Stemphylium*, *Cercospora*, and stem nematodes like *Ditylenchus*); and root rots, vascular wilts and crown diseases (e.g., fungal genera such as *Phytophthora*, *Verticillium*, *Fusarium*, *Phoma*, and bacterial wilt caused by *Clavibacter*).

The major insect pest species that are economically important in alfalfa vary widely among regions in the U.S. The broad geographic distribution of the GT alfalfa test sites in the U.S. and even broader exposure since deregulation in 2005 has exposed GT alfalfa to a wide range of naturally occurring insect pests. The major economic insects included, but were not limited to: potato leafhoppers (*Empoasca fabae*), aphids [pea (*Acyrtosiphon pisum*), blue (*A. kondoi*) and spotted alfalfa aphids (*Therioaphis maculata*)], alfalfa weevil (*Hypera postica*), lygus bugs (*Lygus* species), other plant bug species (family *Miridae*) and alfalfa caterpillars (various Lepidopteran species). The results of the disease and pest susceptibility observations were provided in the final reports submitted to USDA APHIS at the conclusion of the notification period for each field trial. The results from these observations consistently showed no meaningful differences in the disease and insect susceptibility between events J101 and J163 or synthetic populations developed using both events and the conventional control lines or commercial reference varieties. While occasional differences were noted at some field sites, there were no concurrent trends of differences across field sites or years, which indicate that these differences were likely due to random variation. Additional disease ratings taken as part of the phenotypic comparative studies (section VI, subsection D, Petition Number 04-110-01p) support these same conclusions that diseases and pest incidence are unchanged in GT alfalfa compared to the control and that GT alfalfa is not more or less susceptible to pests or diseases.

Commercial experience and additional research conducted since the 2005 deregulation decision further supports previous observations made during the regulated period before 2005. Rhodes (2007) showed that treatment of GT alfalfa with Roundup had no impact on its susceptibility to foliar diseases such as downy mildew (*Peronospora destructor*) when compared to the untreated GT alfalfa control. Monsanto, as part of its product stewardship efforts on commercial products, assesses and addresses product performance issues reported by growers. No reports of changes in susceptibility to diseases or pests have been noted for GT alfalfa since it was introduced.

Given the limited experience with GT alfalfa compared to other GT crops, it is worthwhile considering disease and pest susceptibility information reports from other commercialized GT crops. Several reports suggest that currently available glyphosate-tolerant crops may be more susceptible to infestation by soil-borne plant pathogens than untreated conventional soybeans (Kremer et al., 2000; Termorshuizen and Lotz, 2002). While these preliminary studies show that some changes in population levels of pathogens in soil can occur following glyphosate treatment, there is no evidence of increased incidence of disease in the crop. Other reports in the literature indicate that stress imposed by herbicide application or other common factors experienced in the field can indirectly lead to increased disease in crops (Kawate et al., 1997; Altman and Rovira 1989; Giesler et al., 2002; Dissanayake et al., 1998). Potential differences in the incidence and severity of plant diseases in glyphosate-treated and untreated glyphosate-tolerant soybeans compared to untreated varieties have also been investigated (Sanogo et al., 2000; Sanogo 2001; Lee et al., 2000). Results indicate that the disease susceptibility of glyphosate-tolerant soybeans is no different than that of conventional varieties following application of selected herbicides (Lee et al., 2000; Sanogo et al., 2000).

On the basis of pest and disease susceptibility data reviewed by USDA APHIS, GT alfalfa populations were not different from control or conventional alfalfa populations in the prevalence of disease or pests or in their response to pests or diseases (USDA APHIS 2009). After the deregulation of GT alfalfa in 2005, 200,000 to 300,000 acres of GT alfalfa were established throughout the USA (USDA APHIS 2007). No reports were received or could be found that indicated a change in disease and pest interactions in GT alfalfa compared to conventional alfalfa.

## **4.0 Herbicide Susceptibility**

Considerable data were provided in the Petition to demonstrate that GT alfalfa was susceptible to herbicides that may be used to terminate alfalfa stands (See section VII, subsection F of Petition Number 01-110-04p). According to Crop Data Management System's (CDMS) Ag Product Label Service database indicated that 2,4-D, clopyralid, dicamba, glufosinate, glyphosate, and rimsulfuron-methyl were labeled for control of alfalfa. Independent research has demonstrated that dicamba, 2,4-D, tank mixtures of dicamba and 2,4-D, and clopyralid were often more effective than glyphosate for terminating alfalfa stands (Endres, 1999; Mayerle, 2002; Manitoba Agriculture and Food, 2002). Additional data presented in the Petition (Addendum 1) demonstrated that early postemergence applications of herbicides used to control weeds in corn (Harness XTRA (acetochlor + atrazine), Degree (acetochlor), and Degree XTRA (acetochlor +

atrazine) applied in tank mixtures with broadleaf herbicides Banvel (dicamba), 2,4-D, Marksman (atrazine + dicamba) and Hornet (clopyralid + flumetsulam)) effectively controlled GT alfalfa in a GT corn crop. As expected, J101 and J163 were susceptible to herbicides typically used to control alfalfa.

J101 and J163 are highly tolerant to glyphosate and show no yield loss or loss in forage quality when treated over multiple seasons over and above maximum glyphosate application rates (Pierson and Reyes, 2006). Recommended use rates are provided by Monsanto to growers in Regional Technical Bulletins (appendix U-2 of this technical report) In season maximum application of glyphosate is up to 1.5 lbs a.e./acre at a single application, and total per year applications is 4.5 lbs a.e./acre. These application rates were used by Monsanto when conducting residue studies and for event selection purposes. In practice, these maximum rates will rarely be used since the vast majority of weeds are controlled using recommended rates and it would be uneconomical for growers to apply excess herbicide.

## **5.0 Impact on Agronomic Practices and Changes in Land Use**

The impact on agronomic practices found in section VII of Petition 04-110-01p has been reviewed and analyzed by USDA APHIS. More than 20 million acres of alfalfa have been planted annually since 1950. Acreage peaked in the mid 1960's at 28 million acres and in the last five years has been relatively constant at approximately 22 million acres (USDA NASS, 2006). Based on the adoption of other GT crops, it is expected that GT alfalfa will displace a significant portion of other alfalfa varieties, especially where alfalfa is highly managed (e.g., west and southwestern states). As GT alfalfa is adapted, it is expected that Roundup herbicide will replace other forms of weed control currently used in alfalfa. It is not expected to be adopted in areas where alfalfa is minimally managed and where inputs are low. These areas include pastures, hay fields, and road sides with mixed stands of perennial grasses and other perennial forage legumes and in these same areas in which herbicides are generally not used to control weeds.

Changes in land and the impact of GT alfalfa on land use patterns found in section VII, and Subsections D and F of Petition Number 04-110-01p has been reviewed and analyzed by USDA APHIS. These sections of the petition are relevant to the potential impact of GT alfalfa on land use patterns because they address the impact on agronomic practices and on rotational crops. The impact of GT alfalfa on the overall amount of land devoted to alfalfa cultivation is expected to be minimal. The decision for use of agricultural or other lands for alfalfa production is largely a market-driven decision and the availability of a new weed control option where other options already exist is not expected to impact land use decisions to any great extent. Due to the broad range of weeds controlled by glyphosate, farmers may choose to plant GT alfalfa on fields with greater weed pressure. However, overall land devoted to alfalfa cultivation will be impacted largely by the price of alfalfa hay and not by the availability of GT technology.

Information provided in Petition Number 04-110-01p section VII, subsection F.4 evaluated the impact of GT alfalfa on rotational crop practices including rotations with other GT crops. With the exception of cotton, non-glyphosate-based herbicides are readily available for control of GT alfalfa in common alfalfa rotations; therefore, it was concluded that there would be no impact on

crop rotation practices. Cotton rotations with alfalfa may be managed using mechanical weed control and good stand termination practices.

There has been some speculation that weed-free stands may result in longer stand life resulting in a change in land use. Extended stand life provides positive economic and environmental benefits because a significant amount of the total production costs over the life of the stand are associated with the establishment year. These costs include those associated with seed bed preparation, seed, fertilizer, herbicides and pesticides (Ward, 2007). After the stand is successfully established, costs diminish, and extending a healthy stand will increase profitability. In addition, increased stand life would result in less tillage of agricultural lands and growth of additional alfalfa harvests. Since alfalfa is a plant that provides nitrogen to the soil due to a *Rhizobium*-legume symbiotic relationship resulting in high fixation rates of nitrogen that is usable by the following crop (Vance et al., 1988), growing alfalfa could possibly reduce the need for nitrogen fertilizers obtained through the utilization of fossil fuels.

The introduction of GT alfalfa may provide growers the opportunity to extend the life of a stand because Roundup agricultural herbicides do not cause crop injury like some of the other herbicides currently used on alfalfa. Crop injury caused by an herbicide applied to a crop is described on the label. Herbicide labels are available online at [www.cdms.net](http://www.cdms.net). For instance, the label for Pursuit® (imazathapyr), a commonly used herbicide for control of weeds in alfalfa specifically states that “occasionally, internode shortening and/or temporary yellowing may occur following Pursuit application” and “if applied to alfalfa or clover under cool conditions (40° F or less), temporary stunting or yellowing of the crop may occur.” Similar language is included in the label for Raptor® (imazamox). Eptam® (EPTC: S-ethyl dipropylthiocarbamate) another popular herbicide used in alfalfa also mentions possible crop injury and temporary crop stunting may occur under certain conditions and crop growth stages. Additional information on alfalfa’s tolerance to popular herbicides may be found in state weed control guides (Loux et al. 2007). The tolerance of alfalfa to herbicides commonly used for weed control in alfalfa is presented in table 18 of the guide. The majority of the herbicides are listed as good to fair and only two of the herbicides are listed as excellent. According to the manufacturer’s labels for Pursuit and Raptor, any crop injury is temporary and plants recover with the assumption that there are no impacts on forage nutrition or quality. Thus, removal of weeds in the final years of the stand without crop injury provides the opportunity to maintain a healthy weed free stand. The decision to terminate an alfalfa stand ultimately depends on stand productivity and planned crop rotation practices. Weed pressure is certainly a factor in the decreased production of high quality alfalfa, but they are not the only factor leading to stand decline. Other factors impacting stand life include pest and disease pressure, abiotic stress (e.g., winter kill), harvest practices, rotational crop plans and natural plant senescence as noted in Petition Number 04-110-01p.

## **6.0 Implications to Allergies/Animal and Human Health.**

The U.S. Food and Drug Administration (FDA) is the lead U.S. regulatory agency for review of the food and feed safety of biotechnology-improved crops. FGI and Monsanto completed a

---

® Pursuit and Raptor are registered trademarks of BASF, Eptam is a registered trademark of Gowan.

consultation with the FDA in 2004 (FDA, 2004) on GT alfalfa. The following information relevant to the potential impact on allergies and human and animal health was taken from the FDA submission (Appendix U-2) and from other information reviewed by the USDA (Petition Number 04-110-01p, Addendum 1). The safety assessment of the CP4 EPSPS protein produced in GT alfalfa events J101 and J163 included protein characterization, functional and structural comparisons to ubiquitous plant and microbial EPSPS synthetases with a history of safe consumption, in vitro digestibility in simulated gastric and intestinal fluids, acute oral toxicity in mice, and amino acid comparison to known toxins and allergens. The CP4 EPSPS protein produced by J101 and J163 was isolated from forage and characterized using analytical methods capable of assessing the chemical and functional characteristics of the protein. As a result of the characterization it was concluded that the CP4 EPSPS protein produced by J101 and J163 was biochemically and functionally equivalent to CP4 EPSPSs produced by other GT crops and to the family of EPSPS proteins that naturally occur in crops and microbiologically based processing agents that have a long history of safe consumption by humans and animals. All of these data and information taken together demonstrate a history of safe experience with respect to GT crops which have been consumed in significant amounts, either directly or as processed products, by humans and animals since their initial commercialization in 1996.

Food uses of alfalfa are extremely minor. The majority of limited food uses include consumption of sprouts in many countries throughout the world. Outbreaks of food-borne illness associated with sprouts containing the microbial pathogens *Salmonella* spp, *Escherichia coli* O157:H7 or *Listeria monocytogenes* have been reported. These microbial toxins are associated with alfalfa seed used for sprouting purposes (FDA, 1999; CFIA, 2001) but are not specifically produced by alfalfa. Seed have been identified as the primary source of these microbial contaminants (Puohiniemi et al., 1997; CDC, 1997; Mahon et al., 1997). Therefore, the sprouting industry endorses the use of certified sprouting seed to avoid these outbreaks (International Specialty Supply, 2004).

Documented clinical reactions to alfalfa after ingestion have not been reported. However, respiratory disorders may be exacerbated by alfalfa pollen (Bener et al., 2002; Wilkins et al., 1999). Since alfalfa is not a reported allergenic food and may be a relatively minor contributor to some respiratory allergic diseases, the risk to human health is minimal. The statement that alfalfa is not a reported allergenic food is based on two observations. (1) Alfalfa is not one of the eight foods responsible for the vast majority of food allergic reactions. These foods include peanuts, tree nuts, soy, wheat, milk, eggs, fish, and crustacea (Metcalf et al., 1996). (2) After searching literature databases such as PubMed using key words such as alfalfa and food allergy there were no reports of documented food allergic reactions to alfalfa.

## **7.0 Animal Feeding Studies since the 2005 Deregulation Decision**

*Dairy Cow Feeding Study.* Combs and Hartnell (2007) examined the effect of GT alfalfa forage on feed intake, milk composition and milk production in 16 multiparous lactating Holstein dairy cows. GT or conventional control alfalfa hay was incorporated into diets at 40% of total dry matter. Milk production, milk composition, feed intake and feed efficiency were not different for dairy cows fed GT versus control alfalfa hay ( $P>0.05$ ). GT alfalfa hay has also been fed extensively without incidence since deregulation in 2005. These results confirm those derived

from previously conducted compositional analyses for GT alfalfa where no differences were observed between GT alfalfa and the control, and further confirm the feed safety of glyphosate and the CP4 EPSPS protein.

The safety assessment conducted on J101 and J163 addressed the food, feed, and environmental safety of GT alfalfa. Studies conducted over several years showed that other than tolerance to glyphosate, GT alfalfa populations are no different from conventional alfalfa and are as safe for the environment as conventional alfalfa. The comparative analyses of the composition of GT alfalfa to its conventional counterparts, the safe use of the CP4 EPSPS protein in other GT crops, the practical experience with GT alfalfa by growers, the ongoing use of GT alfalfa as an animal feed, as well as data developed after the 2005 deregulation decision, confirms the environmental and feed safety of GT alfalfa. After reviewing the Monsanto/FGI submission to FDA and other information, APHIS agrees with the FDA assessment and concludes that no concerns exist for the food and feed safety of GT alfalfa vs. conventional alfalfa.

**Appendix V:       Impacts of Roundup Ready Alfalfa on  
Production Practices and Marketing of  
Alfalfa Seed and Hay**

# Impacts of Roundup Ready Alfalfa on Production Practices and Marketing of Alfalfa Seed and Hay

## 1.0 Biology and Culture of Alfalfa

Alfalfa (*Medicago sativa* L.) is a short-lived perennial herbaceous legume (Lesins and Lesins, 1979) and is exclusively an insect-pollinated crop that is pollinated by a small number of insect species, all of which are bees. *Medicago* is in the tribe Trifolieae, which also includes *Trifolium* (true clovers), *Melilotus* (sweetclover), and *Trigonella* (fenugreek). *Medicago* species members do not hybridize with any of these (or other) genera. The *M. sativa* complex has been successfully hybridized with 12 other perennial *Medicago* species (McCoy and Bingham, 1988). However, many of these interspecific hybrids have been successful only by using embryo culture of the hybrid (McCoy and Smith, 1986), making them highly unlikely to occur in nature. No perennial *Medicago* species are present naturally in the Americas, Australia, New Zealand, or South Africa. Therefore, no risk for interspecific hybridization exists in the U.S. However, natural cross-pollination to the scattered naturalized (feral) populations of *M. sativa* is possible. A detailed discussion of the potential for interspecific gene flow is presented in the petition section 2.5 and 2.6. (pages 18-21) and recently was updated (See Document Number 04-AL-116U).

### 1.1 Biological characteristics

A concise, recent review of several salient features of the biology of alfalfa within the context of gene flow was recently developed by an expert panel assembled by the National Alfalfa & Forage Alliance (Van Deynze et al., 2008). This white paper is an in-depth discussion of the potential risks of pollen and seed mediated gene flow in alfalfa growing under cultivated or feral conditions. The key relevant biological characteristics were summarized by these authors as follows:

#### “Growth and Flowering

An alfalfa plant starts its initial growth from a seed during establishment, but after each harvest or winter, it re-grows from buds arising from the perennial root structure (the crown). The vegetative growth interval (i.e. harvest schedule) during most times of the year is 22 to 40 days, and harvest for forage is typically done three to eight times per year depending upon location and seasonal climate. Most of alfalfa in the US is managed to limit growth to the juvenile (vegetative) state in order to optimize forage phytomass production (yield) and nutritional quality of the hay. Hay with late maturity (presence of open flowers or seed) is of poor feed quality and market value. Thus, at any one time, greater than 98% of alfalfa in the US is likely to be without flowers (vegetative) or in an early stage of flower development. It is therefore atypical, sporadic and rare that farmed hay fields sustain flowers, or subsequent to flowering, produce any viable seed. In seed fields, of course, flowering and seed production are promoted. In most fields, flower buds begin to form on stems approximately 4 to 6 weeks after field mowing during long-day photoperiods and

warm weather. Flowering is not triggered under short days or cool weather (i.e., late summer through mid spring). Once flowering ensues, alfalfa flowers indeterminately, and its duration is dependent upon moisture, temperature and other factors.

#### Pollination

Alfalfa is predominantly cross-pollinated and the flowers are entirely dependent upon bees for cross-pollination. Wind cross-pollination in alfalfa does not occur (Viands et al., 1988). Alfalfa requires bees to “trip” flowers to release pollen for ovule fertilization and seed production. In the U.S., alfalfa seed production fields are pollinated primarily with leafcutter bees (*Megachile rotundata* F.) in the Pacific Northwest and honey bees (*Apis mellifera*) in California. Some growers in niche areas of southern Washington use alkali bees (*Nomia melanderi* C.) and certain seed producers use a blend of cultured species for pollination. Native bees, including *Bombus* spp, *Osmia* spp, and *Agapostomen* spp. and native *Megachile* spp. can be found visiting alfalfa in varying numbers. Other insect pollinators have not shown to be effective pollinators of alfalfa.

#### Seed Formation

Alfalfa flowers are cross-pollinated by bees. After pollination of the flowers, alfalfa seed embryos require 4 to 6 *additional* weeks of adequate growing conditions to ripen. Rainfall, low temperature or snow during the ripening time will cause decreased seed yield and poor seed quality (e.g., reductions in seedling vigor and reduced percent germination because of fungal pathogen infection of the seed, or seed will sprout prematurely and die while it is still in the pod). Alfalfa seed is borne in a coiled leguminous pod, and is non-shattering. Natural, non-mechanized, seed dispersal is very local. Alfalfa seed is too dense and smooth for effective wind dispersal.

#### Hard Seed

It is typical for a proportion of the alfalfa seeds in any seed lot to exhibit post harvest latency (“dormancy”) related to “hard seed”. A hard, water-impervious seedcoat temporarily prevents water uptake and delays germination until the hard seedcoat is weathered, aged or abraded. In contrast, seeds maintained dry in storage may remain viable for decades. Alfalfa does not exhibit true, physiological seed dormancy and in most situations the majority of seeds readily germinate. In alfalfa, hard seed is defined as the percentage of seed that do not imbibe water during a standard 72 hr germination test. However, these hard seed have been commonly observed to germinate under field conditions. Undersander et al. (1993) examined rate and extent of germination of alfalfa seed lots varying in hard seed content and found no correlation between the laboratory hard seed rating (% hard seed) and germination in the field.

#### Autotoxicity

Alfalfa plants and alfalfa debris produce compounds that elicit an autotoxic reaction to germinating alfalfa seeds. The autotoxic reaction and inter-plant competition severely limit germination and seedling vigor of alfalfa sown or dropped into existing or newly terminated alfalfa stands. Cultivated fields do not successfully self-seed. Attempts to thicken existing alfalfa stands by deliberately inter-planting new seed into them typically fail, which is why most agronomists do not recommend the practice (Canevari et al.,

2000). Therefore, secondary seedlings are a very unlikely avenue for effective gene flow into existing solid-seeded alfalfa plantings. A portion of seed growers plant their fields in rows instead of solid plantings. In these situations, in-crop volunteers from dropped seeds occur and the resulting seedlings could be a means of gene flow to subsequent crops. However, in order to maintain required varietal and species purity, these seed growers routinely control germinating alfalfa seedlings and weeds using cultivation, irrigation and or soil-active herbicides that do not impact the pre-established, growing crop. The high likelihood of autotoxicity is one reason why growers must rotate to a different crop for at least one full year following stand take-out.

#### Longevity

Alfalfa is a short-lived perennial. Fields grown for hay production are typically maintained for 3 to 6 years or longer in some areas. Commercial production of the alfalfa seed crop is exclusively confined to the western regions of the United States where late season (post-pollination) rain is unlikely, irrigation is carefully managed and specialized alfalfa seed growers, equipment and infrastructure are available. To assure varietal purity, commercial seed production contracts typically require that stands be terminated after three years. Alfalfa is effectively terminated using a variety of mechanical, cultural and or chemical methods. Glyphosate, although somewhat effective in the control of unwanted conventional alfalfa, is not typically used or it is used in combination with other stand take-out practices. Glyphosate will not control Roundup Ready alfalfa (RRA); however, other herbicides and cultural practices remain effective. After cultivated stands are terminated, both seed and hay farmers rotate the field to a different crop species for one or more years wherein alfalfa volunteers can be controlled, if necessary.

#### Feral Alfalfa

Feral plants are crop plants that grow and reproduce outside of cultivation. Feral alfalfa plants can sometimes be found on road edges, in fence lines and in abandoned fields. In the US, feral alfalfa populations have occurred through unintentional plantings of cultivated varieties (“escapes” from cultivation) or, in some cases, they originated from intentional planting of the abandoned fields, roadsides or marginal lands. Feral alfalfa occurs at very low density and scale relative to cultivated alfalfa grown for seed or hay. Biogeographic survey data from six states indicates that for most agricultural areas feral alfalfa plants do not occur or they are sparse (Kendrick et al., 2005). In a 2001/2002 multi-state survey, feral plants were found as dispersed plants or patches within 1.25 miles (2 km) of cultivated alfalfa at only 22% of the survey sites (Kendrick et al., 2005). Feral alfalfa plants are sometimes managed on roadsides by clipping, either with hay being harvested or simply left on the ground along with the other roadside vegetation. Feral plants are sometimes completely unmanaged and given adequate moisture and timely presence of pollinators, can flower and set seed. Feral plants are susceptible to the environmental (e.g. drought in the irrigated West) and insect (e.g. Lygus bugs in the West and potato leafhopper in the East) stresses common to the local area. Although alfalfa was introduced to North America more than 200 years ago, it is not considered weedy, noxious or invasive in cultivated or feral settings.”

In addition to the biological and cultural characteristics summarized by Van Deynze et al., (2008), other relevant features include the following:

## 1.2 Alfalfa in the landscape (feral alfalfa).

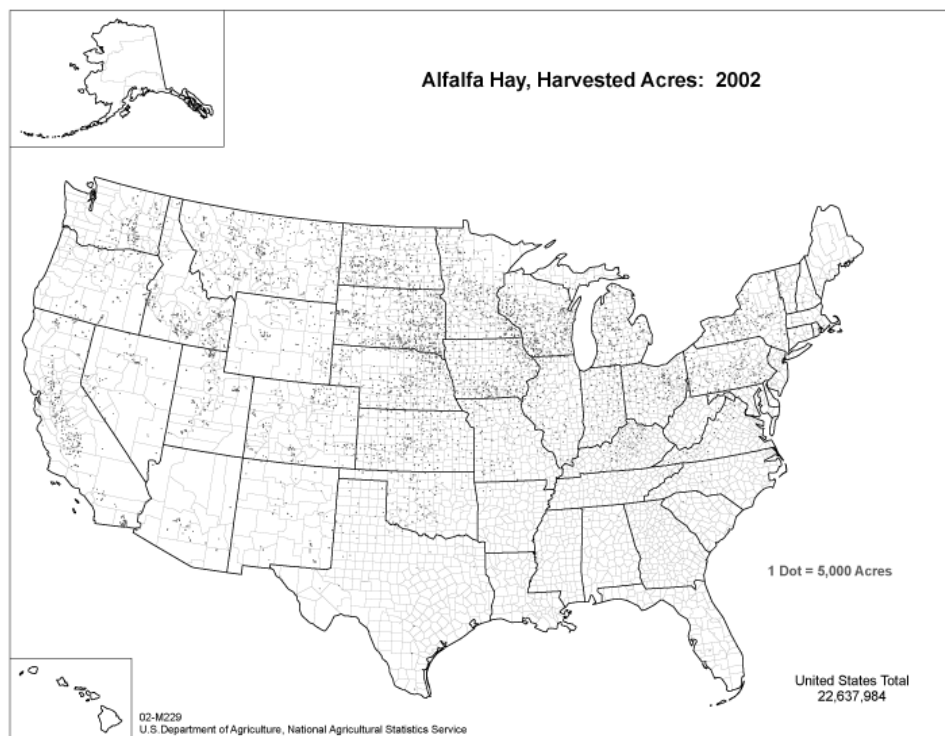

Alfalfa is recognized as the oldest plant grown solely for forage. Alfalfa is an introduced species to the Americas and has become the most important forage crop species in the U.S. and Canada. It is recognized as a widely adapted agronomic crop and grows in all continental states, Alaska and Hawaii. Alfalfa grows optimally in fertile, well-drained soils; however, because of its adaptability, it also survives outside of cultivation. It is not a weedy species and it is not listed as a Federal noxious weed or on other weed lists such as: Federal Noxious Weed List (<http://www.aphis.usda.gov/ppq/weeds/noxwdsa.html>), Washington State Weed Lists ([http://www.nwcb.wa.gov/weed\\_list/weed\\_listhome.html](http://www.nwcb.wa.gov/weed_list/weed_listhome.html)), California Weed Species Lists (<http://www.extendinc.com/weedfreefeed/list-b.htm>), Montana County Noxious Weed List (<http://www.weedawareness.org/weed%20list.html>), North Dakota Noxious Weeds (<http://www.ext.nodak.edu/extpubs/plantsci/weeds/w1103w.htm>).

Where alfalfa exists outside of cultivation, it is typically not targeted for control. In some instances on lands where unmanaged or feral alfalfa now occurs, the planting was intentional (e.g., feral plants exist in relegated sown pastures, abandoned alfalfa fields, or on roadsides once sown with alfalfa seed [see Petition page 375]). All feral alfalfa in the U.S, like alfalfa under cultivation, originated from introduced varieties. Section 5, part 5.5 summarizes the extent of feral populations within six major alfalfa production states of the U.S., confirming that feral populations exist to a minor extent in areas where alfalfa seed or forage is produced. In situations where control of feral alfalfa is desired, just like cultivated alfalfa, it can be controlled or discouraged using cultural or chemical methods (see Petition section VII. Part F and appendix V-4). Because it is unmanaged and genetic resistance to pests is largely absent, feral alfalfa likely is more negatively impacted by endemic pests than alfalfa under cultivation. As a result, the competitiveness and number of viable, vigorous seeds produced by feral alfalfa plants likely are significantly constrained as compared to cultivated alfalfa of improved genetics under management (Van Deynze et al., 2008). Additional discussion of feral alfalfa is presented in section 5 of this document. The issue of the persistence of hard seed and hard seeds contributing to the weed potential of alfalfa is extensively discussed in letters from weed control experts during the USDA public comment period (Docket 04-085-1; e.g., Doll comment #505). Alfalfa does not naturally propagate from vegetative plant parts (e.g., Docket 04-085-1 comment Beuselinck #501).

## 2.0 Forage Production

Alfalfa grown for forage is the third-ranked crop in the U.S. by value and fourth ranked by total acreage. The number and location of alfalfa forage acres are closely associated with livestock operations, especially dairy. Alfalfa is highly valued for animal feed because of its high protein content, high intake potential, and digestibility. It can provide the sole plant component in many livestock feeding programs when supplemented with the proper minerals.

Alfalfa is a deep-rooted perennial that has many economic, soil, and environmental benefits when used alone or in rotation (Hanson et al., 1988). In the U.S. more than 22 million acres currently are grown for forage production (figure V-1). The alfalfa acreage in the U.S. has declined gradually over the past 40 years from a high of approximately 30 million acres (Petition table VII-1, page 255).

**Figure V-1: Geographic distribution of alfalfa forage acres, 2002 (USDA, 2002)**

### 2.1 Stand establishment

Dependent on climate and grower preference, most alfalfa is sown in the spring, except in the western U.S. where fall planting is more common (Hower et al., 1999). Alfalfa can be sown anytime there is available moisture and a sufficient growth period for the seedling that is frost-free (about six to eight weeks). Weeds are the most damaging pest during early stand establishment, especially for spring-sown alfalfa. In order to reduce weed competition, many growers establishing in the spring apply herbicides or co-seed alfalfa with a quick-to-establish

companion cereal crop, such as oat or spring wheat. This practice is especially valuable on wind-swept or sloping land that is prone to erosion. The cereal crop can be maintained until grain set, or more commonly it is harvested immature as forage along with the weeds and the first growth of alfalfa. Companion crops, like weeds, compete directly with the alfalfa seedlings for available moisture, light and space and reduce the amount of harvestable alfalfa forage in the establishment year. Competition or other stress during the establishment period has permanent negative consequences on the overall yield potential of the stand. Therefore, many hay producers “direct-seed” or “clear-seed” alfalfa stands without use of a companion crop. Successful alfalfa sowing requires that the seeds be placed at shallow depth (about one-quarter inch) and that the seedbed is uniform, firm and free of competing weeds.

Most pure-stand alfalfa in the U.S. is established with herbicides, with 52% and 66% of spring and fall planted acres, respectively, treated with herbicides (Hower et al., 1999). About 1.49 M acres of alfalfa are established annually using herbicides (Hower et al., 1999).

## 2.2 Stand longevity

Alfalfa forage production fields remain economically viable for approximately five years after planting. Plants become unthrifty and stands become thin as they age due to the accumulated negative impacts of weed competition, diseases, insects and environmental stress (e.g., excessive cold, heat, drought, and flooding). When terminated, very thin alfalfa stands offer less soil nitrogen to the rotational crop (less rotational benefit) compared to those terminated at higher plant density. Stand longevity is affected by climate, soil type, soil tilth and drainage, autotoxicity, fertility, variety (genetics), and pest impacts. Very short forage harvest intervals generally increase the rate of stand depletion and weed encroachment; very long harvest intervals allow more time for weed seed set. Frequently alfalfa stands may be seriously injured, thinned, or weakened by an interaction between unexpected changes in weather and appropriate use of certain labeled herbicides, resulting in unacceptable weed control.

Often, alfalfa stand length is predetermined according to the grower’s whole-farm crop rotation schedule; typically alfalfa is grown for three to six years followed by at least two years of a non-legume crop (e.g., corn, small grain, cotton, safflower, or vegetables). Expensive-to-control weed infestations can be one reason why forage fields are terminated early.

## 2.3 Stand thinning, impacts of weed encroachment and stand termination

Healthy, productive stands of alfalfa require attention to the management of pests (including weeds), fertilizer inputs, irrigation (if applicable), and harvest timing. Several years after sowing when plants weaken and stands become thin, weeds become more highly competitive with the alfalfa and can contribute to a significant decline in alfalfa yield and forage value. Certain weed species found in alfalfa stands are particularly difficult to control (Hower et al., 1999), are poisonous to livestock, negatively affect palatably or livestock performance, impart off flavors to milk products, and may be noxious to regulated species (e.g., dodder). Alfalfa stands nearly always are terminated using some type of tillage (plowing, disking, roto-tilling, etc.) to help break up roots and crowns, hasten decomposition, relieve soil compaction, and to incorporate this nitrogen-rich plant material as a soil amendment. It is common for many producers to use

tillage integrated with herbicides and or other stand take-out practices (e.g., flooding). Stand take-out is discussed in Petition section VII.B.6 (Pages 259-260). Well-established alfalfa fields or fields undergoing stand renovation are sometimes used for the disposal of livestock manures. Weed seeds present in livestock manure can contribute to an accumulation of weed seeds in the soil and weed problems in alfalfa production systems.

## 2.4 Uses of Alfalfa Hay

In the U.S., the vast majority of alfalfa is harvested as forage for use as animal feed; however, some minor food uses of alfalfa occur such as use of seed for sprout production and the production of forage for human dietary supplements and as tea. In 2005, alfalfa dry hay produced in the U.S. was valued at over \$7.3 billion with 99 percent of it used on-farm or sold within the U.S. (USDA-NASS, 2006) for animal feed. Alfalfa hay export was valued at approximately \$192 million (USDA-FAS, 2006), representing roughly two percent of the total dry hay crop value. Of the domestic use total, less than one percent of alfalfa hay acres were harvested as organic in 2005 (USDA-NASS, 2006). Table V-1 highlights the key export markets for U.S. alfalfa hay. Five countries (Japan, Republic of Korea, Taiwan, Canada and Mexico) account for 98% of the total metric tons exported. Japan imports 74% of the alfalfa exports from the U.S. and is consistently the largest annual importer of U.S. alfalfa hay (table V-1).

**Table V-1. U.S. Forage Export Markets (Metric Tons 1000's)<sup>1</sup>**

<sup>1</sup> Data Source: Department of Commerce, U.S. Census Bureau, Foreign Trade Statistics

<sup>2</sup> This country has approved the import of Roundup Ready alfalfa for feed and food use.

<sup>3</sup> Taiwan does not regulate genetically modified alfalfa.

Conventional alfalfa forage is grown in pure and mixed-species forage systems where it is harvested as dry hay, haylage/silage, greenchop or a lesser extent, grazed in pasture or rangeland. Alfalfa grown in direct-seeded, pure-stand culture is the most likely receiving environment for Roundup Ready alfalfa. USDA statistics are classified separately for each of the harvesting methods (without summary). Except crop classifications labeled specifically as “alfalfa hay” and “alfalfa haylage,” the other various national or state data classifications count acres and hay from other crop species with, and often without, alfalfa present in the stand (e.g., alfalfa-grass mixtures, forage grasses without alfalfa, small grain forages, tame hays, other forage legume species mixtures, wild hays, natural pastures, etc.). Table V-2 summarizes 2006 total hay (and seed) acreage as the sum of “alfalfa dry hay” and “alfalfa hay and haylage” categories only. Tables V-2 and V-3 present 2006 forage (and seed) crop acreage and yield per acre summaries by region and by state.

Most alfalfa forage (“hay”) is used to feed livestock on the farm of production and is not marketed (table V-2). About 40 percent of the national forage production is sold off-farm and is sometimes referred to as “off-farm” or “cash hay.” The average annual price per ton of conventional dry hay has been approximately \$98 per ton (table V-4) during 2001 to 2005. Significant hay market price fluctuations occur within years and among regions, package size, and forage quality grade classifications. High-forage-quality alfalfa hay prices are approaching record highs (~\$200 or more per ton) due to very low supplies: hay stockpiles are at a 30-year low. Record high prices are occurring across many food, feedstuff and energy feedstock crops. However, over the long term, the on-farm value and cash hay sale price of conventional forage is positively correlated with the lot’s objective feed quality value and the subjective appearance of the hay (i.e., green color, absence of weeds, no rain damage, dirt, or mold). The fiber, nutrient and digestibility of hay determine the feed quality value. Commonly, a hay lot is tested and priced according to its forage quality index value. e.g., relative feed value (RFV), relative feed quality (RFQ), or total digestible nutrients (TDN). Within the hay markets, the index values may be used to group the hay lots into “supreme”, “premium”, “good,” “fair,” and “utility” hay grades (USDA-AMS-LGMR, 2006). Hay of supreme or premium grades is often in short supply and may sell for \$50-60 per ton more than average, good, or fair grade hay (Orloff and Putnam, 2004; USDA-AMS-LGMR, 2006).

Due to transportation and storage costs, bulkiness of the hay and relatively low value per truckload, hay is consumed by local livestock and the cash hay markets are local/regional in nature (USDA-AMS-LGMR, 2007). Cash hay often is purchased directly from the grower or sometimes from a hay brokerage at spot sales or alternatively by forward contracting for the scheduled delivery of hay or silage that meets certain minimum forage-quality criteria. Exported hays are grown near large Western port cities. USDA collects sales volume and price data for regional alfalfa hay markets throughout the U.S. (USDA-AMS-LGMR, 2007). These market reports are fragmented by market region/port, lot size, package (bale) size/type, delivery arrangements, forage quality grade, or organic certification status. From this data, it is evident that hay is sold in identity preserved, forage-quality tested lots; it is not fungible. A very small portion of dry hay is processed into hay cubes, feed pellets or sold as individual bales or in small bags at retail stores for horse or pet food. A smaller proportion of alfalfa is consumed by horses, goats, sheep and beef cattle (Putnam, 2005).

Multi-year national statistics for conventional, organic and exported alfalfa *dry hay* acres and values are presented in table V-4 for the 4-year period 2002 to 2005 and an acreage only

comparison for 2006 is presented in table V-2. (Note: 2005 is the most recent year for which organic alfalfa acreage data is available from USDA. Therefore, 2005 is used as the year of comparison for the relative size of organic, export and domestic markets. Dry hay values are used in table V-4 because exported hay is dried before sale or processing.) During the period 2002 to 2006, the number of conventional acres grown for alfalfa forage was relatively stable (tables V-2 and V-4). The 4-year average conventional alfalfa hay production values were 3.33 tons dry hay per acre, \$98.35 per ton, \$311.40 hay per acre, and total market value of \$7.0 billion annually (table V-4).

**Table V-2. Current Markets for U.S. Produced Alfalfa Hay and Seed (acres in thousands) Using 2006 Alfalfa Acreage Data**

**Assumptions:**

Forage:

- Percent used on farm vs. cash crop hay by region (based on polling of regional alfalfa extension experts)
- 0.67% Organic alfalfa hay percent of total acres (based on 2005 NASS report on percent organic all hay).
- 3.0% Non-organic AP-sensitive hay market, percent of total hay (Putnam, 2006).
- 98% GM-sensitive hay to export market, percent exported hay (note: this is based on current market sensitivity, not regulatory issues).

Seed

- Total alfalfa seed export as mean of 2002-2006, as reported by FAS.
- Seed export quantity to Mexico and Saudi Arabia as coated seed, adjusted to estimated raw seed equivalent.
- Percent of certified organic seed production (industry consensus estimate by region).
- 5% Non-organic AP-sensitive seed for domestic markets, AP<0.5% (industry consensus estimate).

## 2.5 Alfalfa hay exports

Certain official statistics for the tonnage of exported alfalfa hay data are highly commingled with and confounded by export statistics for other species crop hays (e.g., USDA-AMS-LGMR, 2007; Woodward, 2006; Putnam, 2005). USDA-FAS (2006) reports estimates for all alfalfa exports, which includes dry hay, cubes, pellets and meal. These hay data are reported by volume (tons), not by acres. Approximately 1.6 percent of the U.S. dry hay crop is exported (table V-4). Most of this exported hay is grown in Washington and California where average yield is 4.9 and 6.9 tons per acre, respectively, and relative to the national average, hay value per ton is high. Using the mean hay yield for these two states (5.9 tons/A), the exported hay represents the equivalent production of approximately 204 thousand acres. It should be noted that an acre producing for the export market during one or more cutting periods likely produces hay for the domestic market at other times of the year (Putnam, 2005) (i.e., fields of alfalfa are not dedicated to the export market per se as they are in organic production). The number of acres from which exported hay is harvested annually is not known (Putnam, 2005). On average, the FAS reported selling price of exported hay is approximately \$160 per ton (table V-5) which is similar to the price for domestically sold hay in the region of production (Pacific Northwest and California). However, using the USDA-AMS-LGMN data, in 2006, within grade, within location, within month, the calculated price paid for export alfalfa hay was approximately 0 to 6 percent lower per ton on average than the price for domestic cattle-use hay of the same grade (calculated from head-to-head comparison of selling prices reported by USDA-AMS-LGMN, 2007). Therefore, in general, export market hay has a similar selling price per ton as other locally available hay; it is not considered a value-added market per se although there is significant value in the ability to contract for a large volume of sales to a few importing customers ahead of harvest time. According to Shewmaker et al. (2006), “The export market helps support and stabilize domestic forage prices in the [Pacific Northwest].” According to a NAFA document addressing coexistence in the alfalfa export markets (NAFA, 2007) the export hay market is of key importance to certain producers in Washington, Oregon and California and coexistence strategies for mitigating the presence of genetically modified (GM) alfalfa should be effective (see table V-5).

Annually, the export hay market is valued at approximately \$192 million (USDA-FAS, 2006) (table V-4). It may be noted that in general, hay sold into the export market channel is of “good,” “good/premium,” or “premium grade. In 2006, no or few “supreme” grade hay lots were exported (USDA-AMS-LGMN, 2007). The highest quality grade hays always are in high demand domestically and locally. The export quality specifications, although affected by objective forage quality grade, can be more sensitive to highly subjective hay attributes (e.g., green color, dirt-free, animal/insect-free) (Putnam, 2005). Approximately three-fourths of U.S. alfalfa hay exports go to Japan each year (table V-1, hay exports; Woodward, 2006); other key alfalfa hay export markets include the Republic of Korea (13 to 16 percent), Taiwan (5 to 7 percent), Canada and Mexico (table V-1, hay exports; Woodward, 2006). More than 85 percent of alfalfa forage exports are hay/compressed bales, with approximately 13 and 1 percent exported as cubes or meal products, respectively (USDA-FAS, 2006).

Table V-4. Total U.S. Alfalfa Hay Acres and Value by Method of Production Practice (2002-2005)

| Practice                                   | Factor | 2002          | 2003          | 2004          | 2006          | Mean          |

## 2.6 Organic alfalfa hay

During 2002 through 2005, the number of acres in certified organic alfalfa hay production increased an average of about 17 percent per year (table V-4). The percentage of total alfalfa hay acres certified as organic per year was 0.58 to 0.91 percent nationally (table V-4). During 2005 (the most recent year for which certified organic alfalfa acres are reported), there were 204,380 acres which was 0.91% of the U.S. alfalfa dry hay total (tables V-4 and V-6). Considering a 17 percent average acreage growth rate per year, the percentage of organic hay acres currently is approximately 1 percent (table V-2). Although the organic dairy and livestock industries are growing very rapidly, organic hay alfalfa acres per se may grow at a slightly slower rate because many of the organic dairy and livestock producers are allowing more access to non-alfalfa (grass) organic pastures (i.e., pure alfalfa is not typically grazed in the U.S. due to the high incidence of bloat). In contrast to conventional hay marketed mainly on forage quality grade, with some exceptions, the main selling criterion apparent for organic hay is often only its organic status per se, irrespective of objective relative feed value (USDA-AMS-LGMR, 2007).

Table V-6. U.S. alfalfa hay (dry) acreage, ranked by number of certified organic acres by state, 2005

\*Sources: Organic acres--USDA, Economic Research Service, based on information from USDA-accredited State and private organic certifiers; standard practice data from NASS.

Most recent year (2005) for which both certified organic and U.S. total alfalfa hay acre data are available for direct comparison.

\*\*Estimate assumes equivalent yield per acre and equivalent forage quality grade for organic and standard practice hays

18% price premium estimate based on median hay selling price for organic vs. non-organic hays of same quality group within the same geography of sale (USDA Livestock, Hay & Grain Market News, 2005 California Annual Hay Report)

The USDA-NASS reports the average conventional hay crop value (\$/ton); however, USDA-ERS does not report the value of organic hay, therefore, it must be estimated. It is commonplace for certified organic feedstuffs to sell for a 10 to 30 percent price premium depending upon demand and local supplies (Long et al., 2005; USDA-AMS-LGMN, 2006). The value-added price per ton for certified organic alfalfa hay is, on average, 18% greater than conventional hay. This price premium was calculated by comparing the mean sale prices of conventional and certified organic hay occurring within each sale location, within each forage quality grade and within each USDA hay market sale reporting period during 2006 (raw data was from USDA-AMS-LGMN, 2006). Certified organic producers often cite that their cost of production is less than for conventional crops, but sometimes there is also a significant reduction in harvestable yield or quality per acre associated with the lessened inputs that limits the value-added profit potential per acre (Long et al., 2005). (Note: Organic forage crop acres are reported to USDA-ERS as “alfalfa dry hay,” “silage,” and “pasture/rangeland.” The latter two categories in ERS count acres of other forage species with-- and largely, without alfalfa. Therefore, silage and pasture/rangeland data used by the ERS are not equivalent in species composition and not directly comparable to similar data categories used by USDA-NASS).

The increased price per ton of hay received by organic growers is partially offset by a substantial reduction in forage quality (due to weeds in the hay) and an approximately 15% reduction of alfalfa yield per acre. (Note: Estimates of 10 to 20 percent (or more) yield reductions were estimated by D. Putnam and D. Undersander, State Forage Extension Specialists from California and Wisconsin, respectively, Personal Communications). The USDA-ERS certified organic alfalfa hay acres were multiplied by these adjustment factors in tables V-5 and V-7. Within each year, calculations were as follows: organic yield per acre = 0.85 x conventional yield; organic price per ton = 1.18 x conventional price per ton; organic value-added = organic value per acre (or per ton) minus conventional value per acre (or per ton). Table V-4 presents organic versus conventional alfalfa hay values for 2002-2005, and, state values are presented in table 6 for 2005. In 2005, only 11 states had more than 5,000 acres of organic hay production. For these 11 states, only seven had more than one percent of alfalfa acres grown as organic, with Idaho representing four percent of the state’s alfalfa hay acres (table V-6). In Idaho, each of eight counties produced more than \$10 million dollars worth of organic certified “other crops and hay” (USDA-NASS, 2002); however, the amount of organic alfalfa hay is not separately reported.

By-region forage (and seed) summary statistics and estimates for 2006 organic acres and regions of production are presented in table V-2, which was compiled by three alfalfa industry experts and presented by McCaslin (2007) to the California Alfalfa Symposium. The panel developed this by-region summary using 2005/2006 official data sets and, when lacking production values, methods or assumptions were estimated, as described in table V-2 footnotes. Contributors to this market summary were alfalfa product leaders of the three largest U.S. alfalfa seed companies: M. McCaslin, Ph.D., President, Forage Genetics International, D. Miller, Ph. D., Alfalfa Research Director, Pioneer Hi-Bred International, and, P. Frey, C.E.O., Cal/West Seeds.

## 2.7 Socioeconomic Factors Influencing Alfalfa Production

Along with its primary value as a high quality livestock feed, alfalfa is a valued rotational crop in U.S. agriculture because it improves soil tilth, fertility and structure. It helps mitigate soil erosion and because alfalfa is a legume, successive crops benefit from residual nitrogen in the soil. Although it is a highly sustainable practice, alfalfa's use in crop rotation is declining in the U.S. because it demands different management, equipment, market channels, and labor schedules not common to other mainstream cropping systems (USDA-ERS, 2002). In addition, livestock to consume the hay may no longer be located in the vicinity. Alfalfa forage-cutting schedules, yield, quality, and persistence are challenged by weather and pests.

In general, alfalfa requires somewhat more complex management and more labor to produce per ton of bulk forage than alternative annual row crops, such as corn silage. In some situations, because of social forces (on-farm labor constraints or other local market changes), forage growers have replaced their alfalfa acres with corn silage, an easier-to-manage, less risky, non-legume forage crop. This has occurred even though the alternative forage crop used is not as environmentally sustainable, is not as nutritionally complete for livestock, and is not as profitable in the long term for many farm systems. The number of alfalfa acres for forage is declining and the number of corn silage acres is increasing. Herbicides routinely are used in corn production, and because corn is grown in rows and is established yearly, there is increased likelihood of more soil erosion compared to alfalfa production. Corn requires nitrogen fertilization; alfalfa does not. Among the corn silage seed choices, forage growers are increasingly adopting varieties with value-added traits, such as herbicide tolerance, insect resistance and other genetically modified attributes that make forage crop production more labor or cost efficient. Therefore, it is likely that such social factors influence a grower's choice to plant alfalfa versus alternative forage species. It is expected that weeds in Roundup Ready alfalfa will be easier, less costly, and less time-consuming to manage compared to weeds in conventional alfalfa plantings.

In part, because of several social and economic reasons, risk-averse producers in much of the U.S. have reduced the number of acres planted to alfalfa. It may be noted that, in contrast to several alternative feedstuff crops, alfalfa crop prices are not directly managed or insured by government programs. Very little hay is transported cross-country and almost none is imported to meet U.S. forage market shortfalls, although dairy and livestock producers require a constant supply. The crop is a perennial that peaks in yield during the second and third year. Relative to annual crops, alfalfa demand and supply are more prone to serious within-season imbalance, price volatility, and the selling price of the alfalfa crop is not known at planting time. Alfalfa growers face the risk of weather interacting with weed competition or herbicide application outcomes that can lead to unpredicted stand failure, stand depletion and or temporary or permanent loss of hay quality or stand yield potential.

In parallel and for several of the same reasons, the numbers of alfalfa seed growers, and seed acres have declined in the U.S. Most alfalfa seed is grown on highly valued irrigated land in the West where there is much competition for the limited number of skilled growers and suitable acres for alfalfa seed growing. U.S. alfalfa seed growers compete with their conventional seed producing counterparts in Canada, Australia and elsewhere, where

comparative production costs are significantly lower (e.g., USDA Docket 04-085-1; public comment by M. Wagoner). Alfalfa seed yield is highly influenced by grower inputs, weeds and insect pests and seasonal weather fluctuations. The cost and availability of required cultured pollinator bees is highly variable (many cultured bees are imported from western Canada).

Similar economic, social and competitive challenges face both U.S. alfalfa seed and forage growers. Weeds increase the level of risk for all alfalfa producers. As has occurred in other agricultural crops, herbicide tolerance in alfalfa may be adopted by producers as a means to mitigate certain weed-associated crop-production risks. The development of new technologies, including but not limited to, herbicide tolerance (e.g., Roundup Ready alfalfa) could act to foster alfalfa culture (in total) so that current production levels are sustained. The Roundup Ready alfalfa technology already has been rapidly adopted and accepted by approximately 4,000 U.S. forage and seed growers who are challenged by a highly dynamic and competitive global marketplace (see numerous USDA Docket 04-085-1 public comments from forage and seed growers).

### 3.0 Seed Production

Alfalfa grown for seed production purposes occurs exclusively in niche areas of the Western U.S. on approximately 100 to 120 thousand acres (figure V-2). Although alfalfa forage is grown in all continental states, the crop value is highest in the West, Plains and upper Midwest.

Additional information on by-county seed production may be found at:

[http://www.nass.usda.gov/Census/Pull\\_Data\\_Census](http://www.nass.usda.gov/Census/Pull_Data_Census)

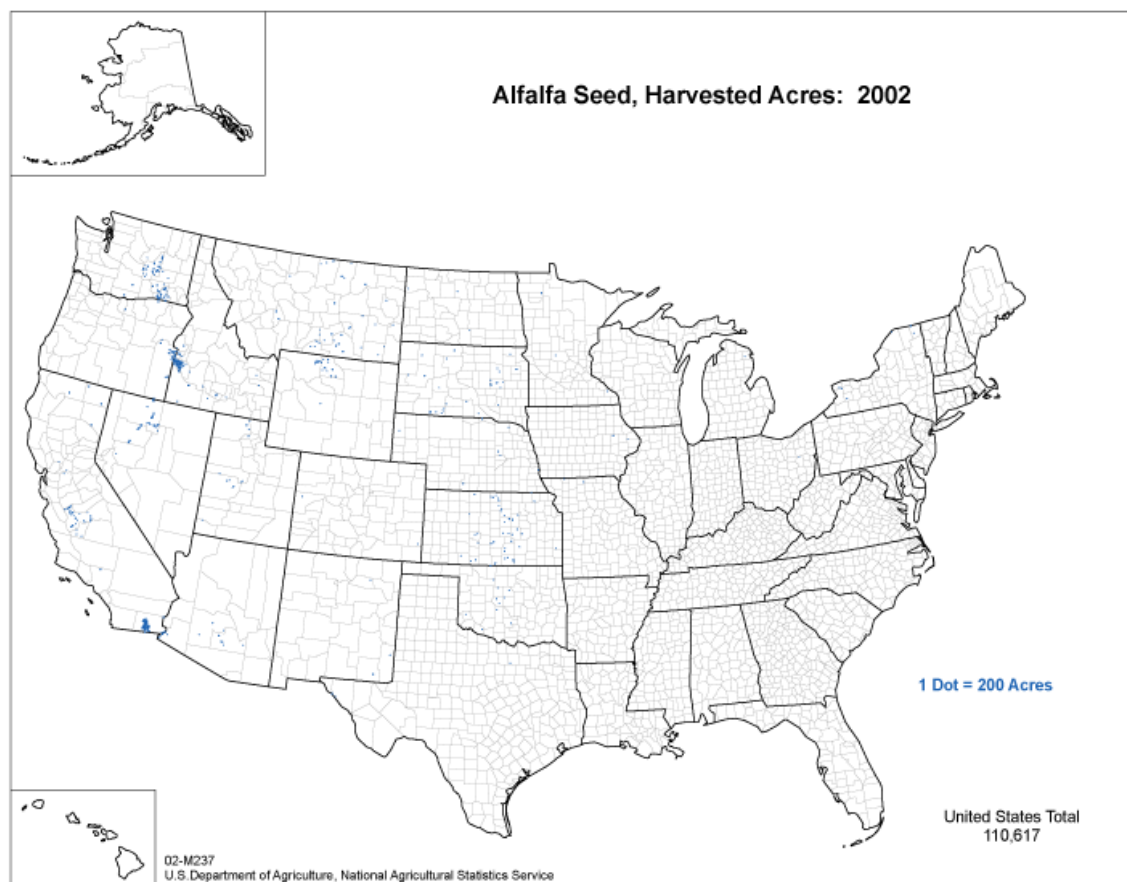

Figure V-2: Geographic distribution of alfalfa seed acres, 2002 (USDA, 2002).

### 3.1 Breeding systems cultivar development

Cultivated alfalfa is an autotetraploid crop that is exclusively bee cross-pollinated. Forage production does not require bees or pollination and seed maturation in forage systems reduces crop nutritional value. Alfalfa is not wind pollinated and it is rarely self-pollinated. Most genotypes do not form any self-seed. Self-progeny are of very low vigor and agronomic value. Discussion of the breeding system for alfalfa was presented in the Petition, section II.

Alfalfa cultivars typically are developed by plant breeders using a combination of phenotypic and or genotypic recurrent selection to identify parent plants. Cultivars are, with few exceptions, open-pollinated synthetic varieties. Seed of the cultivar (or variety) is produced

commercially using bee pollination in isolation from other cultivars (AOSCA, 2003). More than 250 registered conventional alfalfa cultivars are commercially available for planting, and multiple varieties are available from numerous U.S. vendors (>40 seed brands). A list of registered alfalfa cultivars and marketers that sell them are listed in an alfalfa variety list publication offered by the National Alfalfa & Forage Alliance (<http://www.alfalfa.org>). Although U.S. plant variety protection is available to cultivar developers, for the past 20 years, relatively few of the AOSCA registered conventional varieties were submitted by the developer for U.S. plant variety protection. Since 2005, approximately 30 Roundup Ready alfalfa cultivars have been registered within the AOSCA National Alfalfa and Miscellaneous Legume Variety Review Board process. In addition to registered public and proprietary varieties, numerous conventional unnamed brands and common seeds of alfalfa are available for planting.

### 3.2 Commercial planting seeds

The numerous seed alternatives differ in seed quality, adaptation, pest reaction, yield potential, forage quality, tolerance to grazing, degree of winter activity, and many other agronomic features. Alfalfa seed may be sold raw or more typically it is sold pre-inoculated with one or more strains of *Sinorhizobium meliloti* (the alfalfa-nodulating, nitrogen-fixing bacteria) and or coated with lime or clay that may contain a fungicide (e.g., metalaxyl), seed colorants and or micronutrients. Proprietary cultivars often are sold as treated or coated seeds. The retail price for alfalfa seed is related to its agronomic performance, value-added features, quality of the seeds (germination, purity), brand name/seed supplier reputation, annual supply and demand, etc.. The choice of seed is especially important because the decision is made only once in the life of each multi-year stand. The seed price is only two to three percent of the overall alfalfa stand establishment cost. Therefore, the use of high quality seed of superior varieties is a widely recommended practice by university and extension forage specialists. With respect to seed quality requirements and seed labeling laws, state and federal seed control agencies conduct seed lot inspections to ensure truth in labeling. Inadequately cleaned seed lots (purchased alfalfa, grower-saved or bin-run companion crop seeds) can be a potential source of weeds in newly seeded alfalfa.

Essentially all alfalfa hay growers purchase seeds for planting. Due to the unique climate required for successful commercial seed production on alfalfa, there are relatively few producers of alfalfa seed and, therefore, very few alfalfa growers have an opportunity to save seeds should they choose to do so. In most cases, an alfalfa seed producer grows seed of a specific named variety under terms of a seed company contract. Such contracts may require third-party inspection of production conditions and they may prohibit or restrict the practice of saving proprietary seeds grown under the contract. Commercial seed industry practices are discussed in section VII.B.5 and B.7 (pages 259 and 260) of the Petition and further addressed below.

### 3.3 Pollinators of alfalfa

In most alfalfa seed-growing areas, naturally occurring populations of those species of bees capable of tripping and producing cross-pollination are either nonexistent or in such low number that commercial production of seed alfalfa would be impossible without the deliberate production, introduction, and management of certain bee species to provide adequate pollination (Arnett, 2002). Professional alfalfa seed growers use at least one of three species of bees for pollination. They are the honey bee (*Apis mellifera*), the alfalfa leafcutting bee (*Megachile rotundata*), and in very small niche geographies with scattered alkali beds (e.g., Touchet, WA) the alkali bee (*Nomia melanderi*) is used often heavily augmented with cultured leafcutting bees. Feral and native bee species are present in low numbers and pollinate alfalfa. In addition to alkali, leafcutters and honeybees Hammon et al. (2006) identified nine native bee species visiting alfalfa flowers in Colorado.

#### 3.3.1 Distance of cultured and native pollinator travel and or foraging

Although maximum foraging radius for each of the three commercial bee species is dependent on the abundance (or dearth) of nectar and pollen resources, leafcutter bees are considered to have the shortest routine foraging distance (<1/4 mile) followed by the honey bee and alkali bee (ca. 1 to 3 miles) (Arnett, 2003; Hammon et al., 2006; Teuber et al., 2005). There is evidence that honey bees may infrequently transport alfalfa pollen and effect pollination up to 3 miles from the source (St. Amand et al. 2000; Teuber et al 2004; Hammon et al. 2006). Honey bees predominantly work to collect nectar not pollen from alfalfa flowers and they prefer other weed and crop species over alfalfa as nectar sources; therefore, they are less efficient commercial pollinators than leafcutter bees in many regions (Arnett, 2002; Crane, 2002). Cane (2002) determined that honey bees only pollinate (“trip”) only 22 percent of the flowers they visit; therefore, most of their foraging is for nectar, not pollen, and the nectar is obtained by “side feeding” without deposition of pollen or pollination.

In addition to these three cultured bee species, low density populations of bumble bees (*Bombus* spp.) other bee species occasionally visit alfalfa to collect nectar and pollen and may sometimes pollinate alfalfa flowers but their importance in alfalfa pollination is minor (Hammon et al., 2006; Arnett, 2002). Native bees, including *Bombus* spp, *Osmia* spp, and *Agapostomen* spp. and native *Megachile* spp. can be found visiting alfalfa in varying numbers. Non cultured honey bees are not native bees but may occur among the feral bees and although they prefer other plants, they sometimes pollinate alfalfa. Other insect pollinators have not shown to be effective pollinators of alfalfa. Hammon et al. (2006) found evidence to support that, “Most alkali foraging was within seed fields or local in nature,” and that, “Alkali bees were probably of minor importance in long distance pollen movement.” In the Hammon et al. pollinator collection survey (2006), in addition to commercial pollinating bee species, they collected low populations of nine native taxa of bees that may be short, mid and long-range pollinators of alfalfa. Most of the native bees are solitary in nature. A study of the native solitary bees of Germany by Gathmann and Tschardt (2002) found that, “solitary bees have a rather small foraging range so local habitat structure appears to be more important than large-scale landscape structure.” They also determined that, “maximum foraging distance between nesting site and food patch was 150-600 m for the 16 bee species examined,” and that, both foraging distance and mean foraging trip duration (6 to 28 min) were correlated positively with

body length. Therefore, large bees such as *Bombus* spp. may be likely to travel further distances but because they occur in very low numbers and forage on flowers of many other plant species, bumble bees pose a very small risk of significant long-distance gene flow among alfalfa populations.

It is possible that wind storms could blow bees carrying GM pollen long distances; however, due to factors of scale and dilution, the risk of resultant subsequent transgene flow to other alfalfa would be extremely small or zero. In all gene flow studies to date, in addition to the stocked pollinator, native and feral bees were present, so their potential contribution to gene flow under commercial conditions has been accounted for in the available data sets. A general recent review of principles of bee pollination may be found in *Crop Pollination by Bees* (Delaplane and Mayer, 2000). The risk of gene flow at various distances for each pollinator species is discussed in detail in other sections of this document.

### 3.3.2 Commercial pollinator species

The vast majority of certified alfalfa seed is grown under contract in the Pacific Northwest (PNW) and California where seed growers typically introduce and culture either leafcutter bees or honeybees, respectively. Certain seed growers use a blend of pollinator species to optimize seed yield and harvest date. Honey bees tend to tolerate higher temperatures than leafcutter bees. In unique, small geographies of the PNW, the ground-nesting alkali bee may be used to supplement leafcutter bee pollination of alfalfa seed fields or *visa versa*. Bees are introduced and provided with nesting sites (hives, domiciles, or permanent beds) near to or within the seed field. Each of the three commercial pollinator species has different attributes regarding their culture and behavior. When resource-limited, however, bees will scout and range to greater distances but their maximum possible flight distance has not been determined.

The bees are a necessary and costly input for professional seed growers. Growers time the bee introduction release date(s) to coincide with advanced bloom (> 50%) and as bloom resources gradually increase, bee stocking rates are proportionately increased to rapidly and efficiently set the seed crop. These are routine pollinator management adjustments that help ensure that a grower's valuable bees pollinate and remain largely near their home domicile. Approximate stocking rate for leafcutter bees and honeybees is approximately two gallons of loose cell pupae or two hives per acre, respectively; and more or less are applied depending on local bee prices, density of bloom, and seed contract settlement price.

FGI Best Practices for seed growers (<http://www.foragegenetics.com/News.asp>) and Roundup Ready seed grower contracts stipulate the predominant pollinator species to be used, field location and bee management restrictions to be used. If the grower stocks a blend of pollinators, the grower's isolation minimum is set based on the pollinator stocked with the longest foraging range. Once bees are placed in a Roundup Ready alfalfa seed field, the grower is prohibited from moving the bee colony/domicile to a conventional seed field for the rest of the growing season.

### 3.3.3 *Passive physical pollen transfer among bees leading to gene flow*

It is theoretically possible that within colony or when in physical contact, bee-to-bee passive surface transfer of pollen could occur which could lead, rarely, to a subsequent pollination event and gene flow (Mueller, 2005). According to Johansen (1970 Personal Communication as cited by V. Marble), "...bees clean themselves quite thoroughly back at the hive or nest, concluding that little pollen remained to contaminate a new area of [bee] forage when the bees do not return to the same area of a field on the subsequent trip." This suggests that there is near zero potential for gene flow that might result from passive pollen transfer among cohabitating bees and very little accumulation of viable pollen on the surface of bees that make repeated foraging trips to an alfalfa field or feral grouping of plants. There would be essentially no risk of within-nest transfer of pollen for most of the native bee species because they are solitary nesting bees.

### 3.4 Commercial Seed Production

In the U.S., alfalfa commercial seed production occurred on approximately 110,000 to 122,000 acres during 2002 and 2006, respectively. Alfalfa seed production occurs exclusively in the Western states where late-summer seed ripening may occur without damage from rain, heavy dew or high humidity (figure V-2). Alfalfa seed production is a distinct commercial practice from forage production (Hanson et al., 1988). Due primarily to the climate in the West, the U.S. is a major alfalfa seed-producing country. The value of the U.S. annual seed crop is estimated to be in excess of \$90 million. Approximately 70 percent of the seed crop is used domestically.

Key aspects of alfalfa seed production were discussed in Petition section VII B.5 (page 259) and VII.E.2 (pages 286-287). This document describes other practices and characteristics of the U.S. seed production industry with emphasis on stewardship strategies that will enable coexistence among diverse market sectors and preserve grower choice.

Although much alfalfa seed is imported to the U.S. (USDA-FAS, 2006) for planting, some of the imported seeds are reexported by U.S. seed companies. The U.S. is a net exporter of seed (tables V-2 and V-3). Approximately 30 percent of the U.S. seed crop is exported (tables V-2 and V-3).

Alfalfa cultivars are grouped into two main germplasm types: (1) the winter-active, day-length insensitive, "non-dormant" and "semi-dormant" varieties adapted to low deserts and very long growing seasons, or (2) the winter-inactive, day-length sensitive, dormant varieties adapted to the northern latitudes. In general, seeds of each variety type are grown in their respective area of adaptation: dormant varieties in the North and, non-and semi-dormant varieties in Southwest, especially California (table V-2 and table V-3). Seeds also are grouped according to whether they are Certified Seeds. Proprietary varieties are grown under company contract. Public variety and common seeds may be grown with or without a seed contract from a seed company.

The value of alfalfa seed varies widely between years, variety type (proprietary versus common; certified versus non-certified; value-added traits versus none) and quality specifications (germination, species purity, etc.). Official statistics on seed-grower settlement

prices are lacking, but on average, it may be approximately one-half to two-thirds of the wholesale price of seed. Domestic alfalfa seed prices (grower settlement, wholesale or retail) are not reported by USDA-NASS. The only official record of alfalfa seed selling price is for exported seed, not for domestically sold seed and was reported by USDA-ERS for the period 2000 to 2002 (USDA-ERS, 2002). For the period, the average (wholesale) price of Certified and Non-Certified exported seed was \$2.83 and \$2.50 per pound, respectively; these seeds were cleaned, conditioned, packaged for sale, and may be treated coated or raw. A seed value survey conducted by Hower et al. (1999) found that the average growers' raw-seed price was \$1.08 for the period 1988 to 1992, with the overall annual value in excess of \$89 million. In order to approximate an alfalfa seed market value, the recent seed grower settlement price will be estimated as \$1.30 per pound. It should be noted that the sale price that a seed grower receives varies widely (e.g., 0.75 to \$2.00 per pound). Highest prices are paid for contracted, high quality, proprietary production and the lowest for low quality, non-contracted common seeds.

According to USDA-NASS statistics for 2006, 122 thousand acres were harvested for alfalfa seed, total production was 72 million pounds, and the average yield was approximately 590 lbs per acre (weighted average) (table V-3). Using \$1.30 per pound to value the seed, the overall seed production market value was approximately \$94 million. As seen in figure V-2 within the seed producing states, seed production is localized to certain counties. In the most recent USDA-NASS Census of Agriculture (2002), during 1997 and 2002, 1,300 and 1,234 farmers grew alfalfa seed on 163.3 and 110.6 thousand acres, respectively. This is a small number of growers in comparison to those growing alfalfa for forage (i.e., 385 and 344 thousand alfalfa hay growers in 1997 and 2002, respectively). During 2002, 82 percent of the U.S. seed crop tonnage was grown by 314 seed growers operating farms with at least 100 acres of alfalfa seed (USDA-NASS, 2002). Therefore, most of the alfalfa seed production is managed by a relatively small number of large professional seed producers. Nearly all large growers have at least one proprietary seed production contract with one of the four national alfalfa seed production companies. Small acreage seed growers located mainly in the Plains primarily produce uncertified seeds (e.g., for the past several years, South Dakota Crop Improvement has not certified any alfalfa seed production although much alfalfa seed is produced). Overall, approximately 8 and 58 percent of the dormant and non-dormant seed crops are exported (table V-2). The states that export the most nondormant and dormant alfalfa variety seeds are California and Idaho (tables V-2 and V-3). No or virtually no certified organic production of alfalfa seeds occurs in the U.S.

Nearly all alfalfa seed is used for the establishment of hay fields, with a minor amount used as seed field stock seed (variety increase) or for sprouting purposes. Alfalfa seed is not consumed as a grain and therefore not used directly as a food or feed product. Essentially all alfalfa planting seed produced in the U.S. is grown using insecticides and or herbicides, the use of which precludes the seeds' use for food/sprouting purposes. The use of biologically contaminated canal or waste waters or livestock manures to fertilize alfalfa sprout seed fields also are prohibited by food safety regulations. Therefore seed products entering the planting and sprouting seed channels are kept as distinct. A small percentage of U.S. alfalfa seed may be used for sprouting seed. Bass et al. (1988) estimated that 7 percent of U.S. alfalfa seed is

used for sprouting, but this has not been confirmed. Acreage or production of sprout-destined seed is not reported, because field locations for such production are not recorded, they are not known officially. It is believed that most of the sprout seeds are imported because economic alfalfa seed production in the U.S. generally requires the use of some food-prohibited practices. Roundup Ready alfalfa was favorably reviewed by the U.S. Food and Drug Administration in 2004.

#### *3.4.1 Commercial seed production culture*

Alfalfa seed production requires a long growing season with very warm temperature, very low humidity during seed ripening and specialized equipment. Most professional seed producers use cultured bees and specialized equipment associated with bee culture. Therefore, professional seed production only occurs in niche areas of the western U.S. primarily under intensive management and irrigated field conditions (figure V-2).

Cultural practices used to produce seed are distinct from those used to produce forage. Professional seed growers usually grow seed under terms of a two or three year term seed company contract, by variety name. The contracting seed company supplies the stock seed (e.g., foundation seed) to the seed producer and genetic source variety of the seed is documented. In contrast, seed companies purchasing or growing “common seed” or “catch crop” seed typically use lower management and inputs, the genetic identity of the stock seed is often unspecified /unknown and the resultant product quality is highly variable and cannot be certified as to cultivar or variety identity.

Typically, seed fields are planted in the fall and clipped back in late spring so that bloom within the field is uniform, synchronous and optimally timed for the warm dry season and optimal pollinator activity. Weed and in-crop volunteer controls (herbicides and cultivation) are applied mainly prior to the start of pollination or after seed harvest. Flowering begins in approximately mid June. Insecticides (primarily for *Lygus* control) and other pesticides are applied prior to bee release to avoid insecticide damage to the bees. At approximately 50% flower (ca. early to mid July), cultured bees are gradually moved into the seed field for pollination with their domicile or hive for local shelter. The field is actively pollinated for approximately one month, allowed to ripen seed for approximately four more weeks, and then, chemically desiccated or swathed several days prior to combining the seed. At the end of the pollination period and just prior to desiccation, the pollinating generation of bees is either at the end of their lifecycle (i.e., leafcutter or alkali bees) or are transported by the honeybee keeper to a different location to forage on fall-flowering plant species. Seed is harvested in mid August to late September depending on geography. In long-growing season regions, the cool-season alfalfa forage growth between seed crops is sometimes mechanically harvested or grazed.

Usually, stands of alfalfa grown for seed production only are maintained an average of three production seasons. Seed production contracts and AOSCA variety certification standards generally predetermine the length of the seed stand. Because most seed production is planted in widely spaced rows and are not cut monthly, relative to forage stands, weeds in seed fields have more time and open area to proliferate and compete with the alfalfa. Therefore, weeds (and insect) pests are intensively managed in seed production systems. Weed seeds and weed

debris in grower seed lots directly reduce the purity and yield of alfalfa seed and drive up growers' costs to remove them. The presence of prohibited weeds, such as dodder (*Cuscuta* spp.) makes the alfalfa seed very costly to condition and or not saleable.

In 2002, alfalfa seed was grown only on 110,600 acres on 1,234 farms, whereas, the numbers for forage production were 23 million acres and 400,000 (USDA NASS, 2002)(Note: 2002 is the most recent year for which NASS alfalfa seed production full census data are available). In the past 10 years, the alfalfa seed production industry has consolidated and the number of alfalfa variety developers (breeding companies) is small relative to those for other U.S. field crops. Due to the specialized expertise, high-cost of perennial, tetraploid breeding programs and in-part due to a *conventional* alfalfa variety developer's limited ability to protect their proprietary variety from unauthorized increase and sale via common seed channels, there are a small number of alfalfa variety developers. One reason for the small number of variety developers is that, unlike most other crop breeding systems, in conventional alfalfa cultivars, there are no unique, true-breeding genetic markers to help ensure intellectual property, patent rights or plant variety protection rights are respected by unauthorized seed producers (i.e., alfalfa varieties cannot be "fingerprinted" like corn inbreds). Common, variety not stated and or "brown bag" seeds are seed market channels through which unauthorized producers sell improved germplasm of named proprietary varieties without variety developer authorization or knowledge. The unique, event-specific genetic sequence of transgenes will allow genetic fingerprinting of germplasm lines in alfalfa and thereby allow a means to certify cultivar origin, patent rights and trait stewardship. In 2006, there were only four major alfalfa seed companies that developed AOSCA registered varieties *and* produced seed: Forage Genetics International, Pioneer Hi-Bred International, Cal/West Seeds and Dairyland Seeds. In the past five years (2003-2007), in addition to these four companies, approximately three other seed companies and two public institutions have developed and registered new alfalfa varieties (<http://www.NAAIC.org> : NAMLVRB annual lists). In total, there are approximately 60 independent U.S. alfalfa seed companies/conditioners (primary processors) among which FGI is the largest company; approximately 29% of U.S. seed production acreage is produced under an FGI seed contract (Fitzpatrick et al., 2007b).

#### 3.4.2 Seed certification value and standards

Certified cultivar alfalfa seed commands a higher price than uncertified seed; the price of certified seed is also relatively more stable over years. During the 10-year period, 1996-2005, the average and range of retail prices paid by U.S. farmers for certified and uncertified alfalfa seeds were, respectively, \$2.82 (\$2.77-\$2.91) versus \$1.76 (\$1.57-\$2.05) (USDA-NASS, 2006). Hay producers buying certified seeds pay a 60 percent premium over non certified seeds because they understand the value of purchasing seeds of a known cultivar from a reputable supplier to establish a long-term crop. Seed price is approximately 2 to 3 percent of the forage stand establishment cost.

Gene flow between alfalfa populations is a natural occurrence and bee-mediated cross-pollination among plants within a cultivar is necessary for commercial seed production. Alfalfa seed producers use spatial isolation to separate cultivars and manage bee and pollen

flow between fields of different cultivars. The minimum isolation standard for foundation and certified seed fields more than 5 acres in size is 600 and 50 ft, and for fields 5 acres or less, the standard is 900 and 165 ft, respectively [Association of Official Seed Certifying Agencies (AOSCA), 2003]. State seed certifying organizations that are members of AOSCA may adopt the same or more stringent local standards for certified alfalfa seeds. For example, Idaho Crop Improvement Association (2007) requires a greater isolation distance (900 ft) than AOSCA between certified seed fields when one field is conventional and the other is of a genetically modified type (e.g., Roundup Ready). In addition to field isolation, certified seed production applies standards for field history, known genetic origin of the stockseed and in-crop volunteer control to maintain a variety true to type. Variety certification is distinct from organic certification of seeds: variety certification is a product-based certification wherein specified tolerances for off-types and impurities are recognized. USDA organic certification is a process-based certification only; organic seeds or products are not certified according to genetic purity. In a web search of organic seed suppliers, none were found that offered organically grown seeds of a certified variety (FGI: August 14, 2007).

### *3.4.3 Proprietary and public cultivar (variety) conventional alfalfa seed production*

High quality, high value and genetically pure alfalfa seed production requires specialized equipment, pollinators, isolation, climate and unique crop management practices that are not used for forage production. The majority of alfalfa seed tonnage is produced by large professional, specialized alfalfa seed growers using irrigation under multi-year seed company contracts primarily within seven western states (California, Idaho, Nevada, Oregon, Washington, Montana and Wyoming). For example, in 2002, 54 percent of the U.S. seed crop was grown by the 98 large-scale seed growers who harvested greater than 250 acres each (NASS, 2002). The smaller-scale seed growers (< 49 acres each), in total, produced only seven percent of the U.S. seed crop. For the past 20 years, most of the U.S. alfalfa seed crop was produced by registered variety name (known seed source), within official state field isolation inspection programs and under contract for a relatively small number of seed companies that develop or produce proprietary varieties. Due to the specialized expertise and seed conditioning infrastructure required, and in-part due to a conventional alfalfa variety developer's limited ability to protect their proprietary variety (intellectual property) from unauthorized increase and sale via common seed channels, there are a small number of alfalfa variety developers. (Note: Conventional alfalfa genetics preclude genetic fingerprinting of parent or commercial lines.) Less than ten alfalfa variety breeders (companies and public institutions) have officially registered >95% of the AOSCA registered proprietary alfalfa cultivars during the past 20 years (NAAIC-NAMLVRB, 2007). Of the more than 250 listed alfalfa cultivars, fewer than ten public varieties have been released in the past 20 years. The majority of the U.S. alfalfa seed crop is of AOSCA registered proprietary cultivars that are intensively managed by contracted seed growers, plantings are grown to optimize alfalfa seed yield and seed quality using sufficient field isolation, in-crop volunteer control and field history to minimize genetic off-types due to unintended gene flow between conventional cultivars (e.g., using AOSCA field isolation standards (AOSCA, 2003)). Seed of proprietary alfalfa varieties grown to meet official certification standards typically commands a 300% higher market price than common alfalfa seed (US Trade Office statistics for export, 2005). Alfalfa seed companies contracting seed production of a proprietary named variety require that the seed grower plant a company-supplied stockseed lot of the variety (e.g., foundation class

stockseed). Seed growers of certified seeds of public varieties must use foundation seed lots for the variety grown.

### 3.5 Common and organic seed production

Depending on the relative current prices of hay versus seed and amount of rainfall, a highly variable amount of “common” seed is intentionally produced on converted (un-harvested) forage fields or seed fields grown without variety identification, isolation requirement or official seed certification oversight. Common seed, including catch-crop seed and grower-saved seed, is not regulated. Common seed sold inter-state or internationally is subject to phytosanitary regulations (e.g., absence of prohibited weed seeds, diseases and insect, etc.) but cultivar genetic identity or genetic purity cannot be certified.

Organic seed is certified to have been organically produced, but very little if any organic-certified seed is available that is also variety-certified (most organic seed is of common or uncertified varieties sold under a brand name, not by registered variety name). Seed sold under brand name only without a variety name or of an unregistered variety name cannot be variety-certified.

Common seed production occurs mainly in marginal, dryland, hay/seed production geographies (e.g., portions of western South Dakota, North Dakota, western Kansas, western Nebraska, Oklahoma and the Imperial Valley of California, etc.) as a “catch crop” in years of seed shortage (higher seed price), low hay price and or drought sufficient to limit hay yield or feed quality. Most catch crop hay/seed growers are relatively low-input growers and they may or may not apply cultured pollinators to the field and consequently, seed yield and seed quality can be very, very low on catch crop seed. For example, mean seed yield in Nebraska and Kansas was 72 and 100 lbs per acre (1988-1992) versus greater than 500 lbs per acre for states in prime seed growing states (Hower et al., 1999).

Roundup Ready alfalfa seed may not be legally grown as common seed (appendix V-2). In locations of common seed production, Roundup Ready forage producers are obligated to cut their forage fields at or before 10% bloom as a means to mitigate gene flow to conventional common seed fields; see appendix V-2 and terms of Monsanto Technology/ Stewardship Agreement (Monsanto, 2007).

Although a small amount of organic alfalfa seed is purchased in the U.S. from U.S. seed distributors, little or none of the organic alfalfa seeds appear to have been originally grown in the U.S. (McCaslin, 2007 declaration). A National Organic Program Standards exception allows organic forage producers to establish their fields using non-organic (conventionally grown) seeds if their chosen cultivar or cultivar type is not available to them as organic, and after 3 years of adhering to an organic production plan, old hay fields previously managed/planted as conventional may be “converted” into the organic program for organic forage and or possibly for attempted organic seed production. Also, there is an exception for very small organic producers with gross annual revenue of less than \$5,000; no NOP certification is required for the small producer to garner official certification to label their hay

or seed product as organic. It is possible that a low number of economically small organic producers are supplying some organic alfalfa seed to U.S. organic hay producers and because no certification of any type is required, the organic seed and acres used to produce it are unaccounted for in USDA-AMS market census statistics (the volume of seed and the location of production is not officially known). Therefore, although approximately 0.9 percent of U.S. alfalfa acreage is certified as organic (USDA, 2005), only a small fraction of these acres were ever established using organic alfalfa planting seed; i.e., because it is not a requirement, there is little organic seed available. Organically certified and conventionally grown seed lots are routinely marketed to U.S. organic forage producers for the establishment of organic alfalfa forage fields (there are numerous examples on seed company web sites).

Across the western U.S., *Lygus* species bugs are a very serious insect pest on alfalfa seed production (Hower et al., 1999). In California and the Pacific Northwest, the principle U.S. alfalfa seed production regions, virtually every acre of alfalfa seed production is treated with insecticides one or more times each year to control *Lygus* bugs and other insects, and with herbicides to control weeds. In most years and in most fields in the West, complete alfalfa seed crop failure will result without chemical control of *Lygus*. For this reason, organic alfalfa seed production is not economically viable in the prime western U.S. seed growing region.

FGI is the largest producer of alfalfa seed in the world and has extensive first-hand experience in global trade of conventional and certified organic alfalfa seed. In 2006-07, FGI found no publicly available evidence to support that there are any certified organic alfalfa seed producers in the United States. (Disclaimer: It may be noted that due to competitive marketing positions, the external alfalfa seed company representatives polled by FGI and Monsanto may not have voluntarily divulged their company's actual sources of their organic alfalfa seed products.)

Organic alfalfa seed sold in the U.S. by U.S. seed companies is therefore most likely to have been wholly or largely imported from organic producers in Canada or elsewhere, where insect pests in alfalfa seed production are less catastrophic and base production costs for seed are much lower (McCaslin, 2007 declaration). After importation from the country of origin, the seeds may be packaged by a U.S. seed company prior to sale to U.S. organic forage growers; most of this seed is raw or treated only with NOP approved seed treatments and approved *Sinorhizobium* inoculant formulations.

## **4.0 Impacts of Roundup Ready Alfalfa Technology Adoption by U.S. Hay and Seed Producers**

The impact of adoption of the Roundup Ready alfalfa weed control system was discussed in detail in Petition section VII. This section addresses potential agronomic and market impacts as a result of technology adoption of Roundup Ready alfalfa by U.S. forage growers, alfalfa seed-selling companies, alfalfa variety developers and alfalfa seed growers.

### **4.1 Affected Environments**

Roundup Ready alfalfa may affect three primary environments in the United States:

- 1) Agricultural lands where alfalfa is cultivated for hay or seed production purposes;
- 2) Non-agricultural lands and lands adjacent to agricultural lands where alfalfa may be growing without cultivation as feral alfalfa; and
- 3) The human environment, wherein Roundup Ready alfalfa may have social and economic impacts for those choosing to adopt the technology and other impacts for non-adopting producers. Examples of likely non-adopters include conventional alfalfa hay, seed producers serving the organic, conventional as well as export market sectors, and the industries associated with these growers.

Aspects of the affected environments are addressed in detail in the Petition section II (The Alfalfa Family) and section VII (Agronomic Practices and Environmental Consequences). A summary of the affected environments as well as additional relevant information is provided below.

### **4.2 Regulatory Approval Status**

Roundup Ready alfalfa cultivars were initially sold for commercial planting in the U.S. in the fall of 2005. Successful introduction relied upon securing regulatory approvals in the U.S. and key export markets. Prior to market introduction, Roundup Ready alfalfa was deregulated by the U.S. Department of Agriculture, Animal and Plant Health Inspection Service (USDA, 2005) and a consultation was completed with the U.S. Food and Drug Administration (FDA) (FDA, 2004). Use of Roundup herbicide on Roundup Ready alfalfa was approved by the U.S. Environmental Protection Agency (EPA). To support import of Roundup Ready alfalfa hay or seed for food, feed and processing purposes, approvals were obtained from numerous international agencies including those in Japan, Korea, Canada, Mexico and the Philippines. Several countries are also signatories to the Cartagena Protocol on Biosafety (CBD, 2000); thus, regulatory reviews and approval fulfilled their obligation under the Protocol. A listing of key export markets and approvals obtained to date is presented in table V-7.

**Table V-7. Roundup Ready Alfalfa Regulatory Status**

| Country/Sub. | Type of Approval Sought | Approval/Submission Status                                                |
|--------------|-------------------------|---------------------------------------------------------------------------|
| U.S.         | Food/Feed               | FDA Consultation completed December 2004                                  |
|              | Environment             | Deregulation completed by USDA June 2005                                  |
|              | Roundup Label           | EPA approved herbicide labels June 2005                                   |
| Mexico       | Food/Feed               | Food approval completed February 2005                                     |
|              | Environment             | In country production trials in progress                                  |
| Argentina    | Food/Feed/Environment   | Submission planned for early 2008, in country studies underway            |
| Canada       | Food/Feed               | Approved (food and feed), July 2005                                       |
|              | Environment             | Approved, July 2005                                                       |
| Japan        | Food/Feed               | Approved October 2005 (Food); February 2006 (Feed)                        |
|              | Environment             | Approved February 2006                                                    |
| Korea        | Food                    | Approved October 2007 (no feed regulations)                               |
|              | Environment             | Submitted May 2005                                                        |
| Taiwan       | Food                    | Voluntary submission September 2004, only currently regulate corn and soy |
| Philippines  | Food                    | Approval for food, feed and processing, August 2006                       |

#### 4.3 Purpose and Need for a Roundup Ready Weed-Control System in Alfalfa

The benefits of the Roundup Ready alfalfa weed control system were described in the Petition (See section I, subsection C). A brief summary of expected benefits is discussed below. Alfalfa (*Medicago sativa* L.) is a widely adapted perennial species grown primarily for livestock forage in most regions of the United States. Over 20 million acres of alfalfa have been grown annually in the U.S. since 1950. Alfalfa represents the fifth major crop species following corn, soy, cotton, and canola to be improved through the use of biotechnology and is the first perennial to be developed for herbicide tolerance. An important component of alfalfa production in U.S. agriculture is the impact of weeds in alfalfa forage. Weeds consistently reduce the yield of pure alfalfa harvested and negatively affect forage nutritional quality (Peters and Linscott, 1988). Weed management in alfalfa is complicated by the large number of weed species that are of economic importance in the crop. In a U.S. survey, Hower et al. (1999) reported the occurrence of 81 weed species in spring-seeded alfalfa, 93 species in fall-seeded alfalfa and 98 species in established alfalfa. The differences in management required for spring seedings, fall seedings, established stands, pure stands and mixed species culture, in addition to the environmental and economic variables that exist between growing regions, make weed management a challenge in alfalfa. Forty percent of alfalfa forage acres are pure stand, 35 percent are planted with a cover (nurse) crop, and the remaining 25 percent are planted with a permanent companion crop, usually a grass.

Weeds can negatively impact stand establishment, stand density, crop yield, livestock feed value and safety, market price, harvest management timing, and stand longevity. Weeds are a serious stress on alfalfa stands, product quality, and producer profitability. Currently, weed management in conventional alfalfa forage and seed crops is accomplished using an integrated approach that combines cultural and or chemical methods. The normal crop harvest pattern (repeated removal of the hay) controls weeds by interrupting their growth and seed-production cycles. In addition,

field mowing, early harvest, spot burning, site avoidance/selection, planting date selection, co-seeding alfalfa with a cover-crop, crop rotation, and early stand renovation are examples of cultural practices used for weed control, and also negatively impact the alfalfa crop yield and disrupt the local environment to some degree. Numerous non-glyphosate herbicides are widely used in conventional alfalfa either alone or as tank mixtures, in pre-plant, after seedling emergence, and in established stands. These herbicides may be expensive, have a limited window for safe application, cause crop injury, and many times, weeds are not sufficiently controlled so as to warrant the cost or effort to apply. Certain of the herbicides may not be used in later years in the alfalfa crop cycle because they have soil residual activity that may injure a subsequent sensitive crop. Weed and non-native species seeds harvested with the alfalfa are transported with the infested hay mass and transported between farms and over long distances. Certain customers (e.g., those bringing hay into Bureau of Land Management controlled areas) must use hay that is Certified Weed Free. For these reasons, new weed control options are needed in alfalfa.

Herbicides provide considerable agronomic and economic benefits to alfalfa producers and they are essential to alfalfa management in many geographies. According to the 1988-1992 National Agricultural Pesticide Impact Assessment Program Survey (Hower et al., 1999), the majority of pure-stand alfalfa in the U.S. is established with herbicides. Alfalfa is a short-lived perennial species with approximately 20% of the total acres seeded on an annual basis. Of the acres planted each year, 1.49 million acres are pure alfalfa stands and established with herbicides. The overall economic benefit of herbicides used on alfalfa seed and hay acres is \$336 M (Hower et al., 1999). Gianessi et al. (2002) estimated that the value of alfalfa hay in California alone is reduced \$21 M per year because of weeds in harvested hay. Current herbicide programs for alfalfa have several limitations, including application timing restrictions, herbicide carryover and crop rotation concerns, incomplete weed control, and crop injury. While cultural and mechanical weed-management practices are used extensively in alfalfa, they are reported to be substantially less effective than herbicides (Peters and Linscott, 1988). Thus, improved weed control in alfalfa is needed.

Roundup Ready alfalfa will enable the use of Roundup agricultural herbicides to provide effective weed control during forage and seed production. Roundup agricultural herbicides are highly effective against the majority of annual and perennial weeds common to alfalfa seed and forage production. Roundup herbicides also have excellent environmental safety features, such as rapid soil binding (making them resistant to leaching), as well as low toxicity to mammals, birds and fish. In addition, glyphosate is one of the few herbicidal active ingredients classified as Category E by the Environmental Protection Agency (EPA) (evidence of noncarcinogenicity for humans) (57 FR 8739). The Roundup Ready Alfalfa technology offers several key advantages over conventional weed-control methods. Certain glyphosate-containing agricultural herbicides are labeled for use during alfalfa stand renovation (stand take-out), as a pre-plant burn down, and in-crop, during crop dormancy. Roundup agricultural herbicide over the top of Roundup Ready alfalfa will be used to augment integrated weed-control options in alfalfa systems and will offer a unique mode of action for in-crop integrated weed control.

To provide alfalfa producers with an improved weed-control system, Monsanto and Forage Genetics International (FGI) jointly developed cultivars of alfalfa that are tolerant to glyphosate, the active ingredient in Roundup agricultural herbicides. Roundup Ready alfalfa offers alfalfa (forage and seed) producers a new management tool to control weeds before, during and after alfalfa stand establishment, and provides a simpler and more effective weed-control system compared to current alfalfa weed-control practices. Thus, the Roundup Ready alfalfa weed control system simplifies and improves weed management during stand establishment, enhances the flexibility of weed control in established stands, and improves forage quality by reducing the weed content of harvested forage.

Roundup Ready alfalfa cultivars initially were sold for commercial planting in the U.S. in the fall of 2005. The demonstrated benefits of the Roundup Ready weed-control system in alfalfa and other crops and familiarity of the system by farmers resulted in much anticipation and demand for Roundup Ready alfalfa seed. Since 2005 and prior to March 30, 2007, more than 4,000 Monsanto-licensed alfalfa forage producers in 48 states have purchased more than 3.7 million pounds of Roundup Ready alfalfa seed, resulting in approximately 330,000 acres currently planted in the new alfalfa varieties. The supply of Roundup Ready alfalfa seed rapidly sold out in the spring and fall planting seasons. No herbicide-tolerant crop has experienced quicker grower acceptance than Roundup Ready alfalfa, and in California alone, an estimated 20 percent of the 1.1 million acres of alfalfa has been planted to Roundup Ready alfalfa. The benefits predicted for the Roundup Ready alfalfa weed control system met and exceeded the expectations of producers.

Roundup Ready alfalfa has helped forage producers reduce costs and increase income. University of Nebraska conducted studies with the Roundup Ready alfalfa system and showed a 0.2 to 1.0 ton per acre yield advantage in the establishment year over conventional alfalfa treated with standard herbicide programs. This equated to an average net income advantage of \$109 per acre in 2005 and \$91 per acre in 2006 for the Roundup Ready alfalfa system over conventional alfalfa and herbicide programs (Wilson, 2002 and 2006). Not only was more hay produced, but the hay was of better quality. A standard called relative feed value (RFV) often is used to compare nutritive values of hay and forage (University of Wisconsin, 2000; South Dakota State University, unpublished). In a University of Nebraska trial (Wilson, 2005) forage from Roundup Ready alfalfa had an RFV of 208 compared with an RFV of 171 for untreated conventional alfalfa. The cash hay value difference between these hays is approximately \$30 per ton, based on an estimated \$0.80 per RFV quality bonus (Rankin, 2007). This increased yield and quality of alfalfa hay translated into more milk from cows. Research done at the University of Minnesota predicted a dramatic difference in milk production. Based on yield and quality data, Roundup Ready alfalfa would produce an average of 8,204 pounds of milk per acre, compared with 7,568 pounds per acre for the conventional alfalfa— or nearly an eight percent increase (C. Sheaffer, unpublished). A large hay grower in Nevada who commercially used the technology measured a \$190 per acre per year net benefit of the technology over the conventional system (Phillips, 2007, Personal Communication). Testimonies submitted to the court by several growers are provided in Attachment 1 to this amendment. These declarations confirm the economic value provided to growers using the Roundup Ready alfalfa weed control system.

#### 4.4 Agronomic Impacts

Agronomic impacts due to the introduction of Roundup Ready alfalfa were reviewed in the Petition, section VII.

#### 4.5 Impact on Herbicide Practices

A thorough analysis of herbicide options available to alfalfa growers, and the characteristics and limitations of those herbicides were reviewed in the Petition (section VII, subsection D). Based on the adoption of other Roundup Ready crops, it is expected that Roundup Ready alfalfa will displace a significant portion of other alfalfa varieties, especially where alfalfa is highly managed (e.g., Western and Southwestern states). As Roundup Ready alfalfa is adopted, it is expected that Roundup herbicide will replace other forms of weed control currently used in alfalfa.

J101 and J163 are highly tolerant to glyphosate and show no yield loss or loss in forage quality when treated over multiple seasons over and above maximum glyphosate application rates (Pierson and Reyes, 2006). Recommended use rates are provided by Monsanto to growers in Regional Technical Bulletins (See appendix I of Document Number 04-AL-116U-1). In-season maximum application of glyphosate is up to 1.5 lbs a.e. per acre at a single application, and total per-year applications is 4.5 lbs a.e./acre. These application rates were used by Monsanto when conducting residue studies and for event selection purposes. In practice, these maximum rates will rarely be used since the vast majority of weeds are controlled using recommended rates and it would be uneconomical for growers to apply excess herbicide.

#### 4.6 Impact to Rotational Crops and Stand Life

Information provided in USDA Petition Number 04-110-01p section VII, subsection F.4, evaluated the impact of Roundup Ready alfalfa on rotational crop practices, including rotations with other Roundup Ready crops. With the exception of cotton, non-glyphosate-based herbicides are readily available for control of Roundup Ready alfalfa in common alfalfa rotations; therefore, it was concluded that there would be no impact on crop rotation practices. Cotton rotations with alfalfa may be managed using mechanical weed control and good stand termination practices.

There has been some speculation that weed-free stands may result in longer stand life requiring a change in land use. Extended stand life provides positive economic and environmental benefits because a significant amount of the total production costs over the life of the stand are associated with the establishment year. These costs include those associated with seed bed preparation, seed, fertilizer, herbicides and pesticides (Ward, 2007). After the stand is successfully established, costs diminish, and extending a healthy stand will increase profitability. Increased stand life would result in less tillage of agricultural lands and growth of a crop that introduces nitrogen credits, thus diminishing the generation of greenhouse gasses. The introduction of Roundup Ready alfalfa may provide growers the opportunity to extend the life of a stand because Roundup agricultural herbicides do not cause crop injury like some of

the other herbicides currently used on alfalfa. Thus, removal of weeds in the final years of the stand without crop injury provides the opportunity to maintain a healthy weed-free stand. The decision to terminate an alfalfa stand depends on stand productivity and planned crop-rotation practices. Weeds are certainly a factor in production of high quality alfalfa, but they are not the only factor leading to stand decline. Other factors impacting stand life include pest and disease pressure, abiotic stress (e.g., winter kill), harvest practices, rotational crop plans and natural plant senescence.

#### 4.7 Roundup Ready Alfalfa: Overview of Impact on Weed Potential

(Cross reference to Doc 04-AI-116-1)

#### 4.8 Other Roundup Ready Crops: Overview of Impact on the Weed Potential, Disease Susceptibility

(Cross reference to Doc 04-AI-116-1)

#### 4.9 Impacts to Nontarget Organisms

The CP4 EPSPS protein contained in Roundup Ready crops is similar to other members of the EPSPS family of proteins that are common in the environment. Therefore, there is no *a priori* reason to assume that the CP4 EPSPS protein will exhibit adverse biological activity towards non-mammalian organisms or soil microorganisms or associated biogeochemical processes. Further, the introduced CP4 EPSPS itself was derived from a common soil bacterium (*Agrobacterium* sp. strain CP4) and EPSPS proteins are commonly found in bacteria and fungi. Even though the likelihood of hazard is low for the CP4 protein, a number of researchers conducted laboratory and field investigations with different types of arthropods and other non-mammalian organisms exposed to Roundup Ready crops containing the CP4 EPSPS protein. Relevant information for arthropods will be discussed first, followed by soil microorganisms.

##### 4.9.1 *Impact of CP4 EPSPS expressing crops on non-mammalian organisms (arthropods)*

Representatives of pollinators, soil organisms, beneficial arthropods and pest species were exposed to tissues from Roundup Ready crops that contain the CP4 EPSPS protein. These studies vary in design; some for relatively short durations (pest species) and others for multiple generations (*Collembola*) (table V-8). Precise estimates of exposure of the test animals to the CP4 EPSPS protein in most of these test systems were not assessed. Importantly, no toxicity was observed in arthropods exposed to these Roundup Ready crops, reinforcing the conclusion of minimal hazard (table V-8).

The risk assessment for CP4 EPSPS protein in Roundup Ready crops reveals no evidence of unreasonable risk to nontarget animals because minimal hazard is predicted based on widespread occurrence of the EPSPS proteins and no plausible mechanism of toxicity. Although minimal ecological risk is predicted in the formal risk assessment process, several field-monitoring studies were conducted for Roundup Ready crops to reinforce the conclusion and address any potential uncertainties in the risk assessment process (table V-8). Plots were

monitored for arthropod abundance in Roundup Ready 2 Corn, Roundup Ready Soybeans, Roundup Ready Sugarbeet and Roundup Ready Canola. Results of these studies are consistent with the predictions of the ecological risk assessment in that there is no evidence of unreasonable risk demonstrated in these studies. In fact, some of the studies suggest that the Roundup Ready system, the combination of Roundup Ready crops with weed management programs that incorporate glyphosate applications, can promote the abundance of beneficial arthropods through increasing the amount of weed tissue present in Roundup Ready plots.

#### *4.9.2 Impact of CP4 EPSPS expressing crops on non-mammalian organisms (soil microbes)*

Soil microbial communities that mediate biogeochemical processes and directly impact soil quality are highly complex and are often characterized by high microbial diversity (Tiedje et al., 1989). While there is no direct evidence of any hazard to microbial systems from CP4 EPSPS, microbial processes are affected by biotic factors (community characteristics and dynamics, specific plant-microorganism interactions) and abiotic factors such as soil structure, hydration, pH and redox potential (Atlas and Bartha, 1997). In agricultural systems, changes in microbial communities have been observed in response to soil disturbance, history of soil amendment, irrigation, tillage, and plant community structure (Buckley and Schmidt, 2001). Consequently, significant variation in microbial populations is expected in agricultural fields. Furthermore, the individual components of a healthy microbial community within the soil have not been defined with sufficient precision to facilitate risk assessment using specific species as indicators. Although ecological risk predicted for the CP4 EPSPS protein is minimal, independent investigators have studied the potential effects of the purified CP4 EPSPS protein and the Roundup Ready production system containing CP4 EPSPS on soil microorganisms and processes. The distribution and abundance of soil microorganisms, microbial community composition, and microbially mediated processes have been analyzed in field plots containing Roundup Ready Canola (Dunfield and Germida, 2003; Siciliano and Germida, 1999). The results from these investigations confirm there are no meaningful immediate or long-term effects of the CP4 EPSPS-expressing crops on soil microbial communities.

#### **4.10 Impact on Forage Growers**

The Roundup Ready alfalfa technology will be adopted by forage growers seeking a new tool for weed control. It is known that weeds are a more serious economic problem in regions with long growing seasons. Forage growers in regions with higher yield and weed potentials currently have higher input costs into their weed control programs. For example, 50 versus 8 percent of the growers in the West and North Central Regions, respectively, apply non-glyphosate and glyphosate herbicides to alfalfa (Hower et al., 1999). Seeds of Roundup Ready alfalfa varieties will have a higher seed price per pound than conventional varieties but they will allow the added use of a crop-safe, flexible, broad-spectrum and less costly herbicide (glyphosate) for in-crop weed control.

Based on weed impacts, current herbicide use patterns, unmet weed control issues, use of proprietary seeds, prevalence of pure-stand planting, previous Roundup Ready alfalfa seed

sales (2005-2007), and the potential benefits for forage quality and yield per acre, it is anticipated that eventual adoption of Roundup Ready alfalfa will be highest in the Southwest, Plains States, Pacific Northwest (PNW), and Intermountain Regions, and lower in the Midwest, East, and Southeast. During the initial period of deregulation, there was a very strong demand for seeds of the Roundup Ready alfalfa varieties, and virtually all available seeds in the marketplace were rapidly sold and planted. Approximately 300 thousand acres (ca. 4 million pounds of seed) of Roundup Ready alfalfa were planted with some acres in each of the 48 contiguous states. In Monsanto customer feedback surveys, over 95 percent of the early adopters of the technology reported that they were either “very satisfied” or “satisfied” with the product and technology performance.

It is expected that adopters of the new technology will be mainly those growers who are currently higher input, progressive forage growers and those who now purchase higher quality and higher value seeds of alfalfa and of other crop species. Seeds are a small proportion of the cost to establish the multi-year alfalfa forage stand (e.g., two to three percent of the first year inputs). The decision to use improved seeds will be based on local conditions and grower attitudes.

In order to ensure that a sufficient number of alfalfa seedlings establish, the recommended planting rate (pounds per acre) for Roundup Ready alfalfa is the same as that recommended for conventional varieties. The recommended seeding rate varies among geographies, soil types and seeding methods, but it is approximately 12 to 15 lbs per acre in the eastern and northern regions and traditionally as high as 30 lbs per acre in the Desert Southwest. As a means to extend their higher-priced seeds over more acreage or a longer stand life, it is anticipated that some individual forage growers may experiment with planting their Roundup Ready alfalfa seeds at a slightly reduced seeding rate or they may try to maintain their stands one year longer than is customary for their conventional varieties. However, because there are many factors aside from weeds that determine optimal whole-farm profitability, crop rotation schedules (alfalfa stand length) and seedling establishment success, growers would not be expected to significantly alter crop rotation schedules or planting methods should they choose to adopt Roundup Ready alfalfa. It is possible that if growers are presented with any value-added opportunity for the crop or a new effective weed management tool, especially one like Roundup Ready alfalfa that is useful in stand establishment, the total number of acres planted to alfalfa might stop declining (stabilize) or it might slightly increase to some previous level. The number of acres planted to forage crops in total is closely tied to the number of local livestock, so it is unlikely that any large shift in the number or location of alfalfa acres overall would occur. Most producers who are not currently using any herbicides to grow alfalfa are less likely to adopt the technology; they are likely to continue to use companion or cover crops to suppress weeds. All forage producers adopting the technology will combine the use of glyphosate with their routine cultural methods that will act to suppress weeds. Glyphosate can be integrated with other alfalfa herbicides in Roundup Ready alfalfa forage (and seed) production.

**Table V-8. Summary of laboratory, green house and field studies investigating effects in pests and beneficial organisms exposed to the CP4 EPSPS protein and Roundup Ready crops containing the CP4 EPSPS protein compared to conventional varieties**

| <b>Product/<br/>Location</b>          | <b>Type of<br/>Organisms</b>      | <b>Study Description</b>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   | <b>Conclusion</b>                                                                                                                                                                                                                                                                                                                          | <b>Reference</b>               |
|---------------------------------------|-----------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------|
| Roundup Ready Corn (NK 603)/ Thailand | Pollinator (Honey bee)            | Two greenhouse (with single and mixed test material within greenhouses) and a laboratory experiment were conducted to study honey bee foraging behavior, egg laying rate, and in-hive development. Test materials included RR corn, a conventional control and two conventional commercial hybrids. Two beehives were used per greenhouse experiment, and four replicates of 30 bees each per treatment were used in the laboratory experiment.                                                                            | No effects were observed on pollen harvest behavior of workers bees, or on survival and development of honey bee egg, larvae or pupa when exposed to RR corn pollen during and after pollination.                                                                                                                                          | <i>Boongird et al., 2003</i>   |
| Roundup Ready Corn (NK 603)/ Thailand | Aphids & lacewing                 | The experiment was a completely randomized design with 40 aphids and 20 lacewing larvae per treatment. Treatments included RR corn, a conventional control and two conventional commercial hybrids. Lacewings were exposed for 11-12 days to aphids fed on the treatments mentioned above. Measurements included aphid's days for growth development and progeny; and lacewing's days of development to pupa, number of aphids eaten per growth stage, number of eggs per female lacewing and number of eggs that hatched. | No effects were observed on growth or development of aphids feeding on RR corn or of lacewing feeding on the aphids reared on RR corn.                                                                                                                                                                                                     | <i>Jamornman et al., 2003</i>  |
| Roundup Ready Soybean/ U.S.           | Green cloverworm                  | The experiment was a complete randomized design with 30 replicates per treatment. Replicates consisted of individually housed green cloverworms. Treatments included four varieties of soybeans: two RR and two conventional varieties. Measurements included stadia for individual instars and stages, survivorships, and adult morphological measurements as indicators of reproductive fitness.                                                                                                                         | No differences were detected on development and survival of the green cloverworm between RR and the conventional soybean varieties.                                                                                                                                                                                                        | <i>Morjan and Pedigo, 2002</i> |
| Roundup Ready Soybean/ U.S.           | Beneficial species and soil mites | Twelve fields, six planted with RR and six planted with conventional soybeans, were monitored for abundance of 15 major groups of beneficial insects and soil mites. Weeds were managed with glyphosate in the RR soybean fields, and with commercial herbicides in the conventional soybean fields. Arthropods were sampled weekly using sweep nets and pitfall traps. Soil mites were sampled once before fall tillage.                                                                                                  | Results from pitfall traps and soil samples showed no differences in beneficial arthropods or soil mites between RR and conventional soybeans. Results from sweep net samples, however, revealed significantly more green lacewing adults in conventional soybean fields, only when the data from the six fields were pooled for analysis. | <i>Jasinski et al., 2003</i>   |

|                                |                          |                                                                                                                                                                                                                                                                       |                                                                                                                                                                                           |                                |
|--------------------------------|--------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------|
| Roundup Ready Soybean/<br>U.S. | Pests and<br>beneficials | The experiment consisted in four replicate plots (16 rows x 15.2 m) planted with RR and conventional soybean varieties managed under different weed management regimes. Arthropods were monitored during one growing season using a d-vac.                            | No adverse effects on abundance of arthropods were noted relative to RR soybeans. No direct effect of glyphosate applications were observed on arthropod abundance.                       | <i>Jackson and Pitre, 2004</i> |
| Roundup Ready Soybean/<br>U.S. | Collembola               | Collembola abundance was monitored with pitfall traps in a three-year study consisting of eight replicate plots (6.1 x 7.3 m) per treatment. Treatments included RR and conventional soybean varieties under three weed management systems.                           | No differences in Collembola abundance were noted between RR and conventional soybeans under the same weed management system.                                                             | <i>Bitzer et al., 2002</i>     |
| Roundup Ready Soybean/<br>U.S. | Pests and<br>beneficials | Arthropods were monitored using sweep nets in a 1 year consisting of eight replicate plots (6.0 x 6.0 m) per treatment. Treatments included two RR and four conventional soybean varieties under three weed management systems. The study was conducted at two sites. | No adverse affects on abundance of arthropods were noted relative to RR soybeans. Insect abundance was correlated to weed density or plant height.                                        | <i>Buckelew et al., 2000</i>   |
| Roundup Ready Soybean/<br>U.S. | Pests                    | <i>Insect pests were monitored using sweep-nets in a two-year study consisting of four replicate plots (6-8 rows by 15.1 m) per treatment. Treatments included RR and conventional varieties under different weed management systems.</i>                             | <i>No differences on abundance of insect pests were attributed to the RR soybean variety. Differences noted in insect abundance were attributed to factors such as cultivar maturity.</i> | <i>McPherson et al., 2003</i>  |

**Table V-9. Summary of laboratory and field investigations on the potential adverse effects of CP4 EPSPS protein and Roundup Ready crops containing the CP4 EPSPS protein on soil microbial populations compared to conventional varieties**

|                                      |                                                                                                                                                                                                                                                                                                                                                                          |                                                                                                                                                                                                                                                                                                                                             |                                                               |
|--------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------|
| <b>Roundup Ready Canola/ Canada</b>  | Taxonomic diversity of bacteria associated with the roots of RR canola (Quest) and two conventional canola varieties were characterized using fatty acid methyl ester (FAME) analyses. Four randomly chosen plants were sampled from four replicate plots of each cultivar at two sites.                                                                                 | A subtle reduction was observed in the diversity of the bacterial root-endophytic community of a RR canola compared to that of two conventional cultivars. However, the authors concluded that the diversity of bacteria associated with the roots of canola differs between cultivars rather than the presence or absence of the RR trait. | <i>Siciliano and Germida 1999</i>                             |
| <b>Roundup Ready Canola/ Canada</b>  | Characterization of microbial communities associated with the roots of RR canola and conventional canola varieties were characterized using fatty acid methyl ester, community level physiological profiles and terminal rDNA restriction analysis. Plants were sampled over time during a two-year period from four replicate plots of each cultivar at multiple sites. | Principal component analysis showed variation in microbial community associated with canola variety and growth season. The authors concluded that the changes in the microbial community were temporary and did not persist into the next field season.                                                                                     | <i>Dunfield and Germida, 2003; Dunfield and Germida, 2004</i> |
| <b>Roundup Ready soybeans/ Korea</b> | The gene transfer from RR soybeans to soil bacteria <i>Rhizobium</i> was assessed by hybridization using DNA extracted from soil taken from pots. Soybeans were grown in pots for 6 months after which four soil cores (at different depths) were extracted and processed weekly three times.                                                                            | No foreign genes (35S promoter, T-nos or EPSPS) from the RR soybeans were detected in <i>Rhizobium</i> . The results showed no gene transfer between RR soybeans and soil microorganisms.                                                                                                                                                   | <i>Kim et al., 2004</i>                                       |
| <b>Roundup Ready soybean/ Korea</b>  | <i>Possible horizontal transfer between RR soybeans and certain bacteria and fungus common to fermented Korean food were assessed using PCR analysis and antibiotic resistant genes.</i>                                                                                                                                                                                 | <i>The authors did not detect horizontal gene transfer from RR soybeans to food microorganisms.</i>                                                                                                                                                                                                                                         | <i>Shin et al., 2004</i>                                      |

#### 4.11 Impact on Alfalfa Seed Companies and Seed Producers

During the initial period of deregulation, Roundup Ready alfalfa seeds were offered for sale by Monsanto licensed seed companies (i.e., seed brand names). The new Roundup Ready alfalfa seed products (varieties) offer a broad array of licensed seed dealers, distributors and retailers an opportunity to generate new revenues from selling a value-added, trait-differentiated product line.

As a step towards conventional, organic, export, and Roundup Ready alfalfa seed producer coexistence, trait stewardship and gene flow mitigation, the National Alfalfa & Forage Alliance (NAFA) sponsored a stakeholder coexistence workshop (Denver, CO, October 10, 2007). Three of the national seed companies, FGI, Pioneer and Cal/West Seeds, are members of this national alfalfa industry umbrella organization. Under the sponsorship of NAFA, these three seed companies coauthored and have agreed to implement a set of binding, stringent seed production best practices requirements: “NAFA Best Practices for Seed Production of Roundup Ready Alfalfa Varieties” (NAFA, 2007). In addition to these three seed companies, NAFA board members reviewed and accepted the NAFA best practices. Steering committee representatives of NAFA who reviewed and accepted the best practices document included industry stakeholder representatives from seed certification agencies, universities, farmers and companies engaged in the production of seeds and hay for conventional, organic and export market sectors.

There are only approximately 1,234 alfalfa seed growers in the United States (USDA-NASS, 2002 Census of Agriculture). One-quarter of these seed growers (about 300) grow at least 100 acres of alfalfa seed each year, and combined, this group produces about 82 percent of the U.S. alfalfa seed crop. FGI is the largest single alfalfa seed producer in the U.S. and it manages seed contracts for approximately 29 percent of the U.S. seed crop total (Fitzpatrick et al., 2007b).

Weeds directly reduce alfalfa seed yield even though they are heavily managed in alfalfa seed production systems using a combination of cultural practices and multiple herbicides (Hower et al., 1999). Roundup Ready alfalfa offers a new weed control tool and a unique value-added opportunity to U.S. seed growers. Many of them have demonstrated a willingness and capability to grow Roundup Ready alfalfa seeds (see court testimony and public comments to 2005 and 2008 Dockets). During the initial deregulated period (fall 2005 to early spring 2007, professional large-acreage alfalfa seed growers in ten western states produced approximately 4 million pounds of FGI proprietary Roundup Ready alfalfa seeds on approximately 18,000 acres (McCaslin declarations, 2007). Therefore, it may be inferred that among the 300 larger professional seed growers, about one-fourth of them already adopted the Roundup Ready alfalfa technology. Additional seed growers have expressed a strong interest in gaining seed production contracts for Roundup Ready alfalfa varieties from FGI or from Pioneer, the only FGI sublicensed seed producer to-date.

#### 4.12 Impact to Forage Export Markets

Regulatory approval for feed and or food use of Roundup Ready alfalfa hay was granted in Japan, The Republic of Korea, Philippines, Canada and Mexico (see table V-1) and regulatory approval for feed import purposes is not required for import of feeds into Taiwan. Combined, these export markets represent over 98 percent of U.S. hay exports (table V-2). Therefore, hay importer sensitivity to Roundup Ready alfalfa is overwhelmingly a buyer preference decision, not a regulatory issue per se. Insofar as food labeling requirements for biotech-derived foods, some countries, such as Japan, established a five percent GM-trait tolerance threshold for approved trait presence. It should be noted that hay is not a food per se and food labeling regulations are not applicable to feeds. For producers wishing to apply the food regulations as a guideline to their feed import contracts or tolerance limits, trait testing is available. Commercial hay test kits have been developed and independently validated for use in conventional hay testing for the Roundup Ready trait (Woodward et al., 2006). Feed grain and food markets in all of these countries have imported other approved trait GM crops (e.g., corn, soy, cotton, etc.). Therefore, although certain individual hay importers may for now opt to avoid Roundup Ready alfalfa, based on the widespread acceptance in these markets of other Roundup Ready feed crops, it is likely that Roundup Ready alfalfa eventually will be accepted by many foreign hay buyers and dairy producers (Woodward, 2006). Some exporters/importers are particularly averse to weeds in hay and may accept Roundup Ready alfalfa hay to avoid the weeds. However, most individual foreign hay buyers and the U.S. hay exporting companies that serve them are highly GM-sensitive (table V-3).

As stated above, hay export is a niche market but it is an important market in certain geographies of the Pacific Northwest and California where approximately 6 and 1.5 percent of the hay produced, respectively, is exported (Putnam, 2005; Shewmaker et al., 2006). Over 99 percent of exported hay is produced in irrigated acres of the West, primarily in Washington, Oregon, Idaho, Utah, Nevada and California (Putnam, 2005; Shewmaker et al., 2006). According to Woodward (2006) and Shewmaker et al. (2006) nearly 20 percent of Washington's alfalfa hay crop is exported to the Pacific Rim of Asia. Within these far Western states are small niches where sale into the export channel is more common than in others; for example, according to sources cited by Woodward (2006), 35 to 50 percent of Washington's exported hay is grown in the Columbia Basin within the four counties of Adams, Benton, Franklin and Grant. Woodward (2006) estimated that within the Columbia Basin, up to 80 percent of the growers may export at least one of their forage cuttings per year, but this is an estimate for all forage species hays and all growers of all forages, not alfalfa hay alone. According to sources cited by Putnam (2005) approximately 1.5 percent of California alfalfa hay is exported, but as in Washington, alfalfa growers only may sell one or two of their five to eleven cuttings per year into the export channel, so the number of acres harvested for export purposes is higher than 1.5 percent of the total and not known (Woodward, 2006).

A recent document specifically addressed the alfalfa hay export market in the context of gene flow, coexistence and trait mitigation into GM-sensitive hay export markets (Putnam et al., 2007). As described in this NAFA sponsored document, exported hay is sold as identity preserved lots; it is not fungible unless processed. Hay exporters may use hay trait testing, identity preservation of the hay lot, mitigation and avoidance measures to ensure that their hay or planting seeds do not contain the Roundup Ready trait (Putnam, 2006). If an individual lot

of hay were to test positive for the Roundup Ready trait and be rejected by its intended GM-sensitive importer/exporter, there are alternate customers (domestic and or non-GM-sensitive export) available to the U.S. hay producer. Based on export versus domestic market price data, there would be no significant negative price impact for the seller, although the cost of transportation could be affected (if it already were in transit) and buyer-seller delivery contract disruptions would occur if other acceptable conventional hay lots were unavailable as substitutes. Elsewhere in the U.S., little or no hay is exported (table V-3).

#### 4.13 Impacts to Organic Growers and Other GM-Sensitive Alfalfa Producers

A recently specifically addressed the organic alfalfa hay market in the context of gene flow, coexistence and trait mitigation into GM-sensitive organic hay markets (NAFA, 2007). As described in this National Alfalfa & Forage Alliance sponsored document, organic hay is sold as identity preserved lots; it is not fungible unless processed. Organic hay producers may use hay trait testing, identity preservation of the hay lot, mitigation and avoidance measures to ensure their hay or planting seeds do not contain the Roundup Ready trait (Putnam, 2006). If an individual lot of hay were to test positive for the Roundup Ready trait and be rejected by its intended GM-sensitive organic hay buyer, there are alternate customers (general-purpose domestic and or non-GM-sensitive export customers) available to the U.S. hay producer. Therefore, the potential impact on the organic hay producer only would be the difference in selling price (estimated as 18%) not the entire selling price of the hay. Although feedstuffs with detectable GM trait presence are not preferred by organic livestock producers, the presence of GM traits would not cause the lot of hay to lose its USDA National Organic Program (NOP) certified organic status and the lot would still qualify, according to NOP standards, as an appropriate feedstuff for organic livestock. However, the lot of organically produced hay with GM trait presence would not qualify as “GM-free.”

The impact or likelihood of gene flow into an existing GM-sensitive forage field resulting in adventitious presence (AP) of a genetically modified trait in conventional alfalfa is nil and easily mitigated. According to statements by D. Putnam (2007):

“... If an organic grower (or a grower otherwise ‘sensitive’ to the GM trait), plants non-GM seed for hay production near to Roundup Ready alfalfa hay fields, that grower should be nearly 100% ensured of continuing to harvest non-Roundup Ready forage for the life of the alfalfa stand, unless highly unusual circumstances prevail. These unusual circumstances can be prevented with a few simple management practices. [...] There is no evidence to date of any contamination of organic or conventional hay fields originating from Roundup Ready hay fields, and the available scientific evidence demonstrates that the risk of such contamination is almost zero. [...] All of the standard practices in alfalfa hay production work against gene flow. We cut early (usually before flowering) to achieve good quality, so that flowering is not maximized. We don’t deliberately add honeybees or leafcutter bees, which in any event prefer other species, so that

pollination and pollen movement is not maximized. We do not allow seed to develop under normal circumstances to any significant degree since we cut early. The rare seed that is developed is almost always and completely removed with the crop. The occasional rare seed that does develop, remain, and drop to the ground, does not readily germinate and grow in the vigorous canopy of an alfalfa field, as any grower who has tried to seed alfalfa into an existing stand will attest. [...] Thus, in this projection, the probability that pollen from a neighboring GM hay field will contaminate a neighboring organic or otherwise GM-sensitive hay field is 0.0000025%, or 2.5 out of 1 million AP.”

#### 4.14 Other GM-sensitive forage markets

In addition to export and organic hay markets, other hay buyers or conventional forage producers may be sensitive to GM-trait presence such as the Roundup Ready trait. Putnam (2005) estimated that in total approximately three to five percent of the U.S. hay market is now GM sensitive. Table V-3 presents estimates for the other conventional GM sensitive alfalfa producers, by state and by region. Data presented above indicated that 1.6 and 0.9 percent of the sensitive market is accounted for by export and organic markets, respectively. Therefore, approximately 0.5 to 2.5 percent of the remaining hay market may be sensitive to the Roundup Ready trait. This market is composed largely of a subset of horse, dairy goat, pleasure animal and non-organic GM-sensitive conventional livestock producers (Putnam, 2005). Horses are very sensitive to weeds in hay and pure alfalfa hay is not typically fed to horses and non ruminants as a primary feedstuff. It is likely that hay users in this category are sensitive to weeds in hay because many horse and pleasure animal owners purchase individual bales of hay at a feed store. These buyers personally may inspect the quality of the bale. Because of the low-weed or weed-free quality possible with Roundup Ready alfalfa, it is possible that many horse owners, etc., might opt to use weed-free (Roundup Ready) hays rather than avoid them.

## 5.0 Gene Flow: Extent, Impacts, Mitigation, Industry Stewardship and Coexistence Strategies in Cultivated and Noncultivated Settings

Gene flow will occur among and between various alfalfa populations growing in cultivated and noncultivated environments. Therefore, the discussion of alfalfa gene flow is presented between the cultivated and noncultivated environment sections of this document as it applies to both environments. Because of cropping scale and plant density, the opportunity for gene flow will be greater in cultivated settings than in noncultivated settings (Van Deynze et al., 2008).

An in-depth white paper review of gene flow potential and impacts in alfalfa was recently developed by Van Deynze et al. (2008) which was sponsored by The National Alfalfa & Forage Alliance (NAFA). The publication systematically addresses gene flow according to the population interface type, i.e., for gene flow to/from seed fields, to/from hay fields and to/from feral populations—in a total of nine possible combinations as shown in table V-10 (excerpted from Van Deynze et al., 2008). NAFA also sponsored the development of four additional topic papers that were written to assist the alfalfa industry in understanding and managing GM-trait coexistence. Within each topic paper, alfalfa gene flow is discussed with respect to impact and mitigation measures. The four topics are: (1) export hay, (2) export seed, (3) organic alfalfa, and, (4) Best Practices for Roundup Ready Seed Production (see above sections). These topic papers (in press) and the gene flow white paper (in press) will be available from the authors.

**Table V-10. Potential scenarios for pollen-mediated gene flow in alfalfa**

### 5.1 Cultural Practices, Trait Stewardship Tools and Biology Influencing Gene Flow in Alfalfa Systems

As presented above, alfalfa is grown exclusively for livestock forage production purposes on over 22 million acres annually. Greater than 99.5% percent of alfalfa planted in the U.S. is used exclusively for alfalfa hay (forage) production (figure V-1). Approximately 110,000 acres or, 0.5% of the total U.S. alfalfa acres are harvested for seed production (figure V-2).

Alfalfa is a herbaceous, short-lived perennial forage crop species that is predominantly cross-pollinated and entirely dependent upon bees for cross-pollination. Wind cross-pollination in alfalfa does not occur (Teuber, 2007b; Viands et al., 1988). Insect (bee) pollinator activity is required to simultaneously deposit non-self pollen onto the stigma surface and rupture the protective stigmatic cuticle and effect pollination (Viands et al., 1988). Alfalfa flowers have an explosive tripping mechanism that may be triggered by bees visiting the flower to collect nectar or pollen. After it is tripped, the stigma of the flower becomes lodged into the groove of the standard petal of the flower. Because of the nonreversible tripping mechanism within the alfalfa flower, each alfalfa flower may be pollinated only a single time by a single pollinating

bee. While true embryos are found in developing alfalfa pods approximately five days after fertilization (Bass et al., 1988), it takes approximately four to six additional weeks for embryos to ripen to become physiologically mature seed under optimal seed production conditions. High winds and or drought stress may induce flowers to mechanically trip and auto-pollinate; however, it is known that the resulting self-pollination (inbreeding) most commonly results in no seed or few seed and progeny of inferior vigor (Viands et al., 1988).

Flower buds begin to form on stems approximately four to six weeks after field mowing during long-day photoperiods and warm weather. After flowering ensues, alfalfa flowers indeterminately. After pollination, alfalfa seed embryos require four to six additional weeks of adequate growing conditions to ripen. Rainfall or snow during the ripening time will cause decreased seed yield (seed shatters from the pod to the ground) and poor seed quality (e.g., reductions in seedling vigor and reduced percent germination because of fungal pathogen infection of the seed, or seed will sprout prematurely and die while it is still in the pod). Commercial production of the alfalfa seed crop, therefore, is exclusively confined to the western regions of the United States where late season (post-pollination) rain is unlikely, irrigation is carefully managed and specialized alfalfa seed growers, equipment and infrastructure is available (figure V-2). Mean seed yield per acre is greatest in the Pacific Northwest and California (approximately 500-750 lb/A) and very low in the Plains States (70-200 lb/A) (Hower et al., 1999).

The potential for gene flow between alfalfa populations is dependent upon many factors and it is closely tied to agronomic management practice (whether each of the populations or fields are managed for forage production, for seed production, or, if the population is without management, e.g., feral or neglected). Numerous environmental filters that mitigate the risk of gene flow between alfalfa populations growing in various alfalfa settings were extensively described by Daniel Putnam, University of California, Alfalfa and Forage Extension Agronomist (e.g., Putnam, 2006 and 2007), and, Larry Teuber, Ph.D., University of California, Professor of Plant Breeding and Agronomy, Director of the California Foundation Seed Program and Executive Director of the California Crop Improvement Association (Teuber, 2007b). These experts are authorities in alfalfa forage and seed production and breeding systems. In addition, superimposed over the environmental filters are agricultural filters to further mitigate the risk of gene flow. Agricultural filters include customary agronomic best management practices, such as crop rotation, field separation (isolation), equipment sanitation, planting certified variety seeds of known origin, or in some cases, contract-specified identity preservation, or trait stewardship practices (e.g., grower licensing requirements for use of seeds containing GM traits). Key factors affecting gene flow potential are:

- 1) Flowers: Presence or absence; synchrony between populations; duration; relative abundance of in-field (internal) and non-field (external) pollen sources
- 2) Pollinators: Presence or absence; predominant species of bee(s) present; density in relation to floral nectar and pollen resources; preference for alfalfa versus other flowering crops or weeds; temperature and or landscape barriers/incentives to

movement; bee cultivation practices if applicable; presence or absence of insecticide residues that would deter or imperil feral bees.

- 3) Proximity: Physical isolation that mitigates bee cross-foraging (pollen-mediated gene flow), wind-blown pollinators, or, animal, water, wind or agricultural transfer of seeds between populations
- 4) Post-pollination seed maturation conditions: Does the cross-pollinated embryo survive four or more weeks post-pollination to form physiologically mature seed? Does moisture during ripening phase cause nascent embryos to decay or wither in the pod prior to maturation or drop to the ground?
- 5) Seed germination and establishment: Does the cross-pollinated mature seed die soon after sprouting without establishment, or does it germinate, take root and survive despite inter-plant alfalfa autotoxicity and competition with existing vegetation?
- 6) Cultivar selection and cultural practice: Stand renovation and crop removal; crop rotation; timeliness of seed or hay harvest; equipment cleaning and planting seed selection; product handling and segregation; gene frequency in local cultivars; etc.

## 5.2 Pollen-Mediated Gene Flow Studies: Brief Summaries and Key Conclusions

Many studies were conducted which examined the incidence of pollen-mediated gene flow in alfalfa. The key studies were summarized by Van Deynze et al. (2008) and are shown in figures V-3 to V-7. In the 1970s and 1980s, alfalfa scientists used pest resistance and flower color genes to evaluate genetic purity of dissimilar cultivar types produced at various isolation distances between seed fields and along contiguous field edges (Brown et al. 1980; Brown et al. 1986; etc.). The Association of Official Seed Certifying Agencies (AOSCA) alfalfa crop standards committee adopted the recommendations of the North American Alfalfa Improvement Conference Committee on Alfalfa Field Isolation (Brown et al., 1986) to set isolation distances for certified and foundation seed classes (AOSCA, 2003). The AOSCA standards are consistent with established OECD seed certification standards with respect to isolation distance, field history requirements, and genetic purity tolerance for off-types, etc. In the 1990s, other naturally occurring genetic marker systems were used to study the risk of pollen-mediated gene flow between commercial hay, seed and feral plants (St. Amand et al., 2000) and since 2000, the Roundup Ready trait has been used to measure gene flow.

The most recent pollen-mediated gene flow studies (2000-2007) used the Roundup Ready gene as a high sensitivity pollen-marking tool under small, medium, and large field commercial seed and or hay production conditions. V-3 illustrates the various gene flow interface types (types of gene flow) where pollen movement can occur (also see table V-10). In order for true pollen-mediated gene flow to take place, an unbroken chain of six sequential events must occur as shown in figures V-4 and V-5 (Putnam, 2006; Van Deynze et al., 2008).

In addition to pollen-mediated gene flow, seed-mediated gene flow could occur by in-field volunteers (soil seed bank and escapes of stand take-out), seed admixtures during transportation or seed processing, seed transport by water or wind (short distances), seeds in overly mature hay, equipment and animals.

Figure V-3 highlights the key references wherein data have been developed to address the risk of gene flow between each type of pollen flow interface. Gene flow was reviewed in the 2004 Petition appendix 5 for data available prior to April 16, 2004. Since the Petition, Teuber et al. (2005b) have developed an extensive literature review on honeybee pollination and gene flow in alfalfa. The following sections will present the new information since 2004 in combination with previous study data and discussion. As an aid to this discussion, a consolidated gene flow versus distance data illustration by crop setting and pollinator species is presented as figure V-6. Details for each study are found in the original references and numerous key original references will be provided to APHIS with this technical report.

By experimental design, most these recent pollen-mediated gene flow studies estimated pollen-mediated gene flow under somewhat exaggerated and worst-case field conditions. From the standpoint of industry trait stewardship, gene flow mitigation and diverse market coexistence, worst-case studies are an important first-step in gaining an understanding of a novel trait production system. The results from these experiments were communicated to industry stakeholders and to the public. Through consultation with industry stakeholders, the data were used to design FGI's Best Practices Policies for Roundup Ready Trait Stewardship during Seed Production ("FGI Best Practices") in Fitzpatrick et al. (2007b). FGI Best Practices are a set of comprehensive process management requirements that encompass Roundup Ready trait stewardship requirements for licensees, mitigation of unintended gene flow and tools to foster peaceful market coexistence. FGI Best Practices were developed using identity preserved production models, foundation seed production standards and seed quality assurance principles. Data are presented in Fitzpatrick et al. (2007a and 2007b) and personal communication with Miller (2007) that supports the effectiveness of the Monsanto trait stewardship program in combination with the FGI Best Practices policies in attaining successful market coexistence for Roundup Ready alfalfa. Recently, NAFA sponsored a Roundup Ready seed producer Best Practices consensus protocol that was built upon the FGI Best Practices program foundation (2007).

As for other crops with GM trait choices, mitigation and coexistence strategies were developed to allow for the production of high quality alfalfa seed (and hay) to serve diverse market sectors (organic, export, common, conventional and Roundup Ready) and preserve a grower's choice to plant conventional or Roundup Ready seeds. Independent third parties have lead in the industry's development of a broad-based coexistence consensus; examples are the University of California-Davis Seed Biotechnology Center (2005) and the National Alfalfa and Forage Alliance (2007).

**Figure V-3: Cultural practices influence the risk of gene flow among alfalfa populations**

Each type of gene flow interface has been studied. Studies have been collectively reviewed and summarized by Van Deynze et al. (2008).

**Figure V-4: Probability of hay-to-hay field gene flow in alfalfa**

Excerpted from Putnam, 2006

Excerpted from Putnam, 2006

**Figure V-5: Probability of Hay-to-Seed field gene flow in alfalfa**

**Figure V-6: A comparison of the relative gene flow potential for various production systems in alfalfa**

Excerpted from Van Deynze et al., 2008

Gene flow declines with increasing distance from the source. The amount of gene flow is pollinator species and cultural practice specific. Pollen-mediated gene flow is plotted for four specific types of cultivated alfalfa interface types: 1) seed field-to-seed field under honey bee pollination (Teuber et al., 2004); 2) seed field-to-seed field under leafcutter bee pollination (Fitzpatrick et al., 2003); 3) mature (20-50% flower stage) hay field-to-seed field data sets combined for leafcutter and honey bee pollinators (Teuber and Fitzpatrick, 2007); and, 4) estimated hay field-to-hay field gene flow (Putnam, 2006).

**Figure V-7:** Pollen-mediated seed-to-feral gene flow observed from three-year-old commercial “Roundup Ready” seed fields (900 acres overall) to small feral and unmanaged alfalfa clusters

Gene flow was measured by evaluating 33 seed samples collected from 23 small clusters of feral or intentionally unmanaged alfalfa plants in western Colorado (raw data was excerpted from Hammon et al. 2006). The nearby Roundup Ready seed fields were commercially pollinated with cultured leafcutter bees, and, various species of native bees, alkali bees and honeybees were also intermittently present and pollinated the alfalfa. Median sampling distance and gene flow were 0.5 mile and 1%, respectively. There was no correlation (ns) between amount of gene flow and distance from the nearest field. The Roundup Ready seed production fields were in the third consecutive seed production year. Within the survey zone, virtually no sources of conventional pollen were present to cross-pollinate the feral plants except for that from other small, dispersed patches of feral/unmanaged or forage field plants and forage fields cut at early maturity.

Key conclusions from alfalfa pollen-mediated gene flow studies are discussed in the following three sections.

5.2.1 *Forage fields as the pollen-receiving environment, i.e. fields grown for hay, haylage, pasture or greenchop*

5.2.1.1 Hay-to-hay

“Hay into hay” pollen-mediated gene flow is essentially zero and can be reduced to zero with normal forage harvest management practices (Putnam, 2006 and 2007). Figure V-4 illustrates the environmental filters that act against effective gene flow between adjacent hay fields.

5.2.1.2 Seed-to-hay

“Seed into hay” pollen-mediated gene flow is likewise extremely improbable because the pollen receiving hay field would not be grown to produce any viable seed. Pollen and pollinators would be present because of the proximity of the seed field. If rare, viable cross-pollinated seed were to form on the forage field stems, it is highly unlikely that seeds in the forage mass still will contribute to gene flow because they rarely will establish new plants (Putnam, 2006; Cash, D., 2005, Personal Communication; and Cash, D., public comment 481 to USDA/APHIS Docket 04-085-1). The amount of pollen-mediated gene flow into a GM-sensitive conventional or organic forage field can be reduced to zero when the GM-sensitive forage field is harvested prior to seed maturation.

5.2.1.3 Feral-to-hay

“Feral into hay” pollen-mediated gene flow is also essentially zero and can be reduced to zero with normal forage cutting management practice on the GM-sensitive hay field (Putnam, 2006 and 2007). The amount of pollen-mediated gene flow into a GM-sensitive conventional or organic forage field from (likely infrequent) GM-feral plants can be reduced to zero when the conventional forage is harvested prior to seed maturation and or nearby feral plants are mowed prior to bloom or eliminated by herbicides and or cultural methods. Feral plants have not typically been targeted for control and in most situations, glyphosate would not be the herbicide of first choice to control it (see Petition, section VII.F.6. and Petition appendix 3). The paucity of feral plants coupled with the low frequency of the Roundup Ready gene in feral populations will constrain the amount of Roundup Ready feral pollen available to the hay field in the local environment. There would be little or no selection pressure on future feral alfalfa populations toward glyphosate-tolerant genotypes in plants or pollen. Even if feral alfalfa were left unmanaged, factors of scale, asynchrony, low pollinator density and other environmental and agricultural filters in the cultured fields would make it high improbable that gene flow to occur from feral plants into a hay field.

## 5.2.2 *Seed fields as the pollen-receiving environment*

### 5.2.2.1 Hay-to-seed

“Hay into seed” field pollen-mediated gene flow potential is zero to near zero with observance of routine AOSCA certified isolation distances (e.g., 165 ft) and or normal forage field cutting management practice ( $\leq 10\%$  bloom cutting) during the seed field pollination period. Figure V-5 illustrates the environmental filters that act against effective gene flow into seed fields from hay field sources. If because of weather factors or mechanical problems, a neighboring GM forage field is harvested at a later stage of maturity (e.g., 20 to 50% bloom) during the peak seed-pollination period, the potential for gene flow into a nearby small seed field is very low (e.g., 0.3% for distances less than 165 ft). With greater isolation, it is exceptionally rare (e.g., for 350-600 ft isolation, mean flow was 0.01%) (Teuber and Fitzpatrick, 2007). These values are at least ten-fold lower than predicted from worst-case seed-to-seed gene flow models. Therefore, current AOSCA isolation requirements for certified seed production (165 ft) are sufficient to mitigate gene flow from typical hay fields into conventional certified seed fields to low levels. Where feasible, highly GM-sensitive seed producers can lessen further the risk of pollen-mediated gene in-flow to their seed field from other/unknown varieties of hay by choosing to use larger size seed fields ( $>5$  acres), stocking pollinator species that range shorter distances (i.e., leafcutter bees vs. others), harvesting the seed field border as a separate lot (St. Amand et al., 2000; Fitzpatrick et al., 2007a) and working to coexist with their neighbors who grow alfalfa for forage (e.g., ask them to their cut their hay early during mid-summer or to use non-GM varieties). Organic, export, common, or foundation class seed producers who are highly GM-sensitive can opt to work with local crop improvement organizations and use wider isolation or buffer zones with identity preserved practices for their GM-sensitive seed fields (e.g., follow the most conservative AOSCA foundation seed class standards which require use of 900 ft or greater isolation to any different alfalfa variety whether grown for hay or seed purpose).

### 5.2.2.2 Seed-to-seed

“Seed into seed” field pollen-mediated gene flow is a common, measurable, natural occurrence for proximal seed fields of different cultivars. Conventional certified variety seed growers largely rely on physical isolation to minimize and mitigate pollen-mediated gene flow. The quantity of pollen-mediated gene flow between adjacent seed fields was extensively studied for the past three decades and the data used to develop current AOSCA and OECD seed isolation and production standards. The percentage of pollen-mediated gene flow into a seed field is dependent upon field isolation distance, bloom synchrony, cultural practices, in-crop volunteer management, gene frequency in the pollen, pollinator species present, density, available food resources, and shelter placement.

Under actual commercial conventional seed grower conditions, the use of pollinator-species specific isolation minimums and identity preserved production protocols have successfully mitigated GM gene flow to levels observed for other GM crop species and produced seeds of high genetic purity, i.e., seeds of greater than 99 percent genetic purity, and, AP level at zero to less than 0.2% (Fitzpatrick et al., 2007a and 2007b). The amount of actual gene flow under

commercial-scale (large field) conditions is several times less than is predicted by research models developed using smaller-fields (Fitzpatrick et al., 2007a and 2007b).

This most recent data set developed using the Roundup Ready trait supports the findings of previous gene-flow research studies wherein conventional traits were used as pollen markers in large and small fields. Small fields or feral patches have a higher relative percentage of pollen in-flow than larger fields (AOSCA, 2003; Brown et al., 1986; Fitzpatrick et al, 2007a and 2007b; Hammon et al., 2006; Marble, 1980 circa; St. Amand et al., 2000). Therefore, the predictive models developed using smaller field trap sizes (or isolated alfalfa feral trap patches) were very constructive in that they offer worst-case predictions for pollen-mediated gene flow, but they significantly overestimate pollen flow into larger more typical commercial fields. For small- to mid-scale seed-into-seed field settings, gene flow declines sharply with increasing distance from the source (see figure V-6 and supporting references).

As required by Roundup Ready seed production contracts and NAFA Best Practices for seed production (NAFA, 2007), Roundup Ready seed producers will continue to report the locations of all Roundup Ready seed fields to their local crop improvement organizations. These independent third-party agents will maintain Roundup Ready seed field location records and field histories. GM-sensitive seed producers, therefore, have an available mechanism to obtain GM alfalfa seed field location information and request professional services to assist them in seed field isolation planning. As stated above, where feasible, many GM-sensitive seed producers can lessen further the risk of pollen-mediated gene in-flow from other/unknown varieties of seed (or hay) by choosing to use larger size seed fields (e.g., >5 acres), stocking pollinator species that range shorter distances (i.e., leafcutter bees vs. others), harvesting the seed field border as a separate lot (St. Amand et al., 2000), and working to coexist with their neighbors who grow alfalfa for forage and seed. Organic, export, common or foundation class seed producers who are highly GM-sensitive can opt to use additional isolation or buffer zones and identity preserved practices for their GM-sensitive seed fields (e.g., follow the most conservative AOSCA foundation seed class standards which require use of 900 ft or greater isolation to any different alfalfa variety whether grown for hay or seed purpose, etc.). In addition, groups of local seed growers can use informal or formal conventional-only seed production zones. NAFA Best Practices stipulates that Roundup Ready seed producers will not contract for Roundup Ready seed production in such grower organized zones.

Commercial seed lot data validate that implementation of the Best Practices system is a very effective industry tool in the management of conventional seed lot genetic quality (Fitzpatrick et al., 2007a and 2007b). Adventitious presence of the Roundup Ready trait in conventional seed lots has been infrequent and in all cases well below the 0.5% industry consensus AP tolerance for domestic alfalfa and below values predicted using worst-case research models. The large-scale commercial validation also helps put in perspective the minimum incremental risk associated with potential real world concerns about pollination from wild pollinators, extraordinary pollen flow by wind-driven pollinator movement, and contamination through physical mixtures of seed in harvesting and/or seed processing.

The data of St. Amand et al. (2000) and Fitzpatrick et al. (2007a) supports that a conventional border (or buffer) area is a sound gene flow mitigation strategy for producers of highly GM-

sensitive seed crops (the border could be of the same conventional variety as in the field center). The outside edge could be harvested separately and tested, and if no GM-trait is detected in the border seed, it could be bulked with the main field lot. It should be noted, however, that if, as St. Amand et al. suggest, a conventional cultivar were used to border a GM-containing seed field or research plot, the genetically different variety border would violate seed certification isolation standards (i.e., the genetically dissimilar border would preclude variety certification of the main field seed crop). Moreover, even for non-certified seeds lots, especially small experimental lots, the encompassing conventional pollen would negatively affect GM seed crop's trait percentage and genetic purity.

During the development of field-isolation standards, AOSCA and other certifying agencies have considered data from fields and plots with little or no isolation (e.g., <100 ft.). Data sets developed using conventional traits indicated that although there is a very minor amount of gene flow between seed fields (Brown, et al., 1986) or within seed fields (St. Amand et al., 2000) bulking of seeds throughout the field help mitigate the percentage of whole-field off-types to industry and AOSCA accepted levels (<1% off-types).

Seed growers who are highly GM-sensitive may opt not to apply the 10% rule or any other exceptions to isolation in the production of their seed crop whether or not it is officially certified as to varietal purity. Specifically, the AOSCA certified class seed standards (2003) have a "10 percent rule exception" as follows:

- 1) "Minimum distance from a different variety or fields of the same variety that do not meet the varietal purity requirements for certification, shall be 600 and 300 feet for fields over 5 acres; and 900 and 450 feet for fields 5 acres or less that produce the Foundation and Registered seed classes, respectively.
- 2) "Isolation requirements for the certified class are based on the size of the certified field and the percentage of the field within 165 feet of another variety of alfalfa. If 10 percent or less of the certified field is within the 165-foot isolation zone, no isolation is required - only a definite separation. If more than 10 percent of the field is within the isolation zone, that part of the field must not be harvested as certified seed. The isolation zone is that area calculated by multiplying the length of the common border(s) with other varieties of alfalfa by the average width of the certified alfalfa field falling within the 165-foot isolation distance requirement.
- 3) "In those cases where a portion of the field meets isolation requirements, then a clear line of demarcation shall be established between the certified and non-certified portion of the field."

#### 5.2.2.3 Feral-to-seed

"Feral into seed" field pollen-mediated gene flow potential will be zero or very, very low and it can be reduced to zero or near zero when the GM-sensitive conventional seed producer mows feral alfalfa to prevent synchronous bloom or takes steps to eliminate feral alfalfa plants (see mitigation strategies discussed for seed-to-seed conditions, above). There is evidence that conventional seed producers already are managing against the presence of feral alfalfa in seed-growing counties of Idaho and California (Kendrick et al., 2005). Even if feral alfalfa were left

unmanaged, factors of gene frequency (feral plants may be genetically conventional or GM in type), factors of scale, asynchrony of bloom, low pollinator density in the feral areas and other environmental and agricultural filters in the cultured seed fields would make GM gene from feral plants into a seed field from feral plants extremely improbable or very low occurrence. As described in the previous section, the conventional seed field edge, if harvested separately as a border crop, may be used to further mitigate the potential for gene flow from feral alfalfa into seed fields. 2000).

### *5.2.3 Feral alfalfa plants as the pollen-receiving environment and feral plants as bridges for GM (Roundup Ready) gene flow*

Long-distance pollen and seed-mediated gene flow from GM (e.g., Roundup Ready) commercial-scale seed and blooming hay production settings into feral alfalfa populations will occur (Hammon et al., 2006; Kendrick et al., 2005; St. Amand et al., 2000). In locations where feral alfalfa is of concern to GM-sensitive seed or hay producers, it can be controlled or reduced so that the economic impacts will be negligible or nil (Kendrick et al., 2005; Petition appendix 3; Van Deynze et al., 2008). Large-scale feral or volunteer alfalfa patches can be a potential bridge for gene flow between managed seed or hay fields and within and among feral plant groups. It is important to note that many bee pollinators avoid collecting pollen or nectar from alfalfa flowers when other flowers (weeds or crops) are growing in the vicinity. Biogeographic survey data from six states indicates that for most agricultural areas feral alfalfa plants do not occur or they are sparse (Kendrick et al., 2005). Alfalfa is not considered invasive or weedy, so unless feral plants are actively humanly encouraged—as has occurred in the past (Petition page 375), it is unlikely that feral alfalfa populations or their role in pollinator or pollen-bridging would expand above current levels.

In California and Idaho, feral alfalfa was observed at fewer survey sites within counties where intensive alfalfa seed production occurs relative to those in counties where alfalfa is primarily grown for forage (Kendrick et al., 2005). This may indicate that professional, certified seed growers in California and Idaho are already controlling feral alfalfa as a means to ensure certified seed crop genetic quality or at a minimum, producers in these counties are not actively encouraging alfalfa to grow outside of cultivation (e.g., non-cultivated areas are not irrigated). Also, these seed growers would see a benefit from mitigating feral, escaped, unmanaged alfalfa patches because such unmanaged plant patches act as a reservoir of alfalfa seed insect pests (e.g., *Lugus*) which are detrimental to seed yield and physical quality.

According to Mueller (2005), in California, “feral or volunteer alfalfa grows rampant along roads and ditch banks, in fallow fields, and as a weed in cropland throughout the state, [and that,] it can provide a bridge for pollen movement from production fields to other fields. A good stewardship program [for biotech alfalfa] includes grower education concerning control of volunteer plants using mechanical or chemical alternatives and preventing viable seed set in volunteers.” To meet this objective, prior to the first commercial release of Roundup Ready alfalfa, FGI and Monsanto had incorporated feral and volunteer plant control education and seed field stand-take out requirements into the Roundup Ready alfalfa stewardship program.

Feral population densities are low. For example, in Colorado, Kansas and Washington when researchers conducted pollen-mediated gene flow into feral populations, the researchers opted to

simulate (cultivate) higher than locally occurring feral plant densities: i.e., the researchers either opted to transplant artificial pollen-trap plant populations along a roadside (St. Amand et al., 2000) or the augmented the number of available “feral” seed collection sites by intentionally leaving a network of hay field patches non-harvested so that they would simulate feral alfalfa and form cross-pollinated seeds (Hammon, et al., 2006). This indicates that even near intensive seed production locations, the researchers did not find a sufficient number of escaped feral plants to conduct their desired study design.

Until the recent advent of GM alfalfa, feral, roadside, escaped, relegated fields and volunteer alfalfa plants have been largely ignored by non certified seed growers or encouraged to proliferate (e.g., planted intentionally along roadsides with occasional harvest during drought seasons). Due to factors of alfalfa biology, bee biology, pests affecting feral alfalfa, relative population size, proximity, low likelihood of feral seed recruitment and establishment, and, a seed grower’s ability to control feral alfalfa through mowing during the pollination period or elimination by non glyphosate methods, future Roundup Ready feral plants will pose a very unlikely source of gene flow into GM-sensitive commercial seed (or hay) production. Seed production experts (e.g., Brown et al., 1986), gene flow data (St. Amand et al., 2000; Fitzpatrick et al., 2007a; Marble, 1980) and AOSCA foundation seed production standards (AOSCA, 2003) support that the potential risk of gene flow is scale-dependent. Therefore, the relative size, density and proximity of feral patches to one another and to nearby blooming cultivated alfalfa (i.e., the size of any competing pollen source) will affect both the frequency of GM traits in feral populations and the likelihood that feral plants will act as bridges for GM-trait gene flow. It is expected that over many sexual generations, the frequency of genotypes (conventional and or GM) in local feral populations will reach genetic equilibrium with locally grown commercial plantings if there is bloom synchrony and cross-pollination. The rate and extent for feral-to-feral population GM-trait gene flow will be affected by many environmental and agricultural filters (Putnam 2006). In the absence of glyphosate exposure, there is no adaptive benefit to feral plants containing the Roundup Ready gene versus their conventional counterparts. According to Van Deynze et al. (2008), “It is expected that only a minor portion of the seeds formed on the feral plants will result in true gene flow. Most seeds formed on feral plants will likely perish; as most would fail to successfully germinate, compete or establish outside of cultivation.”

Feral alfalfa occurs at very low density and scale relative to cultivated alfalfa grown for seed or hay. Gene flow into small fields has been studied extensively; however, the reverse—gene flow out of small fields or feral patches into large seed fields has not been. St. Amand et al. (2000) determined that gene flow is common between feral plants and that it likely occurs at short (0 to 4 m) and long distances (several miles). St. Amand et al. (2000) demonstrated that within an alfalfa seed field, pollen egress from a 1 meter diameter point source (similar in size to a patch of feral plants) could not be detected beyond 4 meters from the genetically marked pollen source plants. Dense patches of feral alfalfa, although not managed or protected from pests, could have similar bloom synchrony and comparable within patch gene flow dynamics to managed seed fields (but seed yield and quality would be much lower). St. Amand et al. found that, within seed fields:

“Movement of the marker within the field occurred only over very short distances [and at low frequency]. Only 0.2% of the progeny 4-m away from the marker plants carried the marker gene and no progeny 6-m away were detected with the marker. Of those progeny carrying the GS marker, 97.4% occurred no more than 2-m from the source plants. Clearly, within-field gene movement only occurs over very short distances. It is likely that pollen is being cleansed [groomed] from the pollinators or is being covered with non-marker pollen after repeated visits to non-marker plants. This finding indicates that borders surrounding seed production fields may be useful in decreasing or limiting gene flow outside of a field.”

Pollen cleansing or occlusion would be expected to occur on bees traveling long and or short distances among feral plants. Bee behavior or pollen dilution of conventional with GM pollen would be expected to constrain the rate and extent of Roundup Ready gene flow into and among feral plant populations.

### 5.3 Gene flow mitigation via Roundup Ready Licensing: Trait Stewardship Overview

A comprehensive product licensing and stewardship program has been developed for Roundup Ready alfalfa. The program is a critical component to the successful long-term use of the technology for weed control in alfalfa. A summary of the commercial trait stewardship program is presented as appendix V-2 and key elements are highlighted in this document when they pertain to trait stewardship, mitigation of gene flow and or successful marketplace coexistence. All Roundup Ready forage producers are obligated to a core set of Monsanto trait stewardship license requirements and they are educated on the importance of their role in trait stewardship. Monsanto has an auditing program to ensure licensee compliance to the terms of the trait agreements.

Separate and in addition to the Monsanto requirements, all Roundup Ready seed producers are subject to an additional layer of licensing and contracting. Forage Genetics is the exclusive Monsanto licensee enabled to perform Roundup Ready Alfalfa seed production. Through sublicensing agreements, Forage Genetics will contract with a small number of qualified, professional seed growers or seed companies to increase commercial quantities of Roundup Ready alfalfa varieties (e.g., approximately 76 alfalfa seed growers were contracted during 2006-07, exclusively in the U.S.). In addition to the Monsanto license requirements, each FGI Roundup Ready seed producer is contractually obligated to adhere to the FGI Best Practices. FGI has an auditing program to ensure licensee compliance to the terms of the FGI Best Practice trait agreement for seed producers. The field isolation at planting for Roundup Ready seed producers is extraordinary in that the minimums are pollinator species specific and they are five to 95 times the current isolation requirement for conventional certified seed production. Extreme isolation at field planting (3 miles) is observed for fields in California where much seed is exported and honeybees are the preferred pollinator species. The FGI/NAFA Best Practices isolation distances are illustrated in figure V-8.

**Figure V-8: Roundup Ready alfalfa Best Practices for seed field isolation at planting**  
 (presented by Fitzpatrick)  
 (Fitzpatrick et al., 2007)

At planting the location of all Roundup Ready alfalfa seed fields is reported to local crop improvement and the isolation distance to the nearest conventional alfalfa field is inspected. GM-sensitive seed producers may use this information to plan their field locations.

#### 5.4 Gene Flow in Forage Crop Management Systems, Additional Comments and Background Information

As an animal feedstuff, alfalfa's optimum economic value per acre occurs just as the vegetative growth period is transitioning into the flowering phase (Sheaffer et al., 1988). Therefore, forage producers have a strong economic disincentive to allow mature seed set in hay production. Flowers and developing embryos—although briefly present in a hay field, are removed along with the vegetative growth before pollination or seed ripening. Therefore, because the fields have few flowers, most forage fields do not attract or support the nutritional needs of foraging bees. Livestock forage producers do not, therefore, introduce any bees into the forage fields.

Unlike seed or grain harvest, forage production periodically removes the entire plant canopy where flowers, pollen or seed might form (Sheaffer et al., 1988; Putnam, 2006; Putnam, 2007). After forage harvest, growth of the new vegetative canopy must be reinitiated from crown buds (as occurs in the spring) or from the elongation of lower stem axillary buds. Hence, some of the issues regarding uncontrolled proliferation of a trait will not biologically impact alfalfa managed for forage production because pollen is available to pollinators for a very limited duration and/or no ripened seed will be produced under typical cutting management (Putnam, 2007; Cash, D., personnel communication). In a forage field, in the unlikely event where viable physiologically

mature seeds are produced and dropped to the soil, the resultant germlings are unlikely to be successful in self-perpetuation because of intense inter-plant competition and effects of autotoxicity (Tesar and Marble, 1988; Putnam, 2006 and 2007; Undersander, 2005; Canevari et al., 2000; Cash, D., 2005, Personal Communication; and Cash, D., public comment 481 to USDA/APHIS Docket 04-085-1). There is strong evidence that even when alfalfa seeds are intentionally inter-seeded into an existing alfalfa field—a practice known as “over-seeding”, such introduced seed fail to establish (Canevari et al., 2000). Seed dropped near feral alfalfa plants have the same and additional barriers to successful establishment outside of cultivation (Cash, D., public comment 481 to USDA/APHIS Docket 04-085-1).

As in an alfalfa seed production field, a seed-bearing forage or feral alfalfa plant is more likely to have been pollinated by neighboring plants due to pollen-ovule proximity, local pollen abundance and within-field bloom synchrony. For example, St. Amand et al. (2000) measured no detectable cross-pollination within a (seed) field beyond 4 m from the pollen source plant. Moreover, when or if a rare cross-pollinated Roundup Ready seed forms in a conventional forage field the seed may fall from the pod or it may be subsequently transported out of the field by harvesting equipment, in the harvested forage mass or via water, wind, soil or animal defecation. Just like conventional alfalfa, the rare Roundup Ready cross-pollinated seeds will only very rarely result in the establishment of a successful new plant (Putnam 2006 and 2007). Gene flow into hay fields, whether from a neighboring seed field (Teuber, 2007b), hay field or feral population or grazing animal, etc. is very unlikely to result in any gene flow due to numerous biological, agricultural and environmental barriers discussed above. Alfalfa, whether of conventional or Roundup Ready derivation, is not a weedy plant *per se* although alfalfa may be targeted for control in certain crop rotations and non crop settings.

The impacts, mitigation and potential for gene flow between, into or out of alfalfa forage production fields has been recently extensively reviewed by Van Deynze et al. (2008) and previously by Daniel Putnam, Extension Agronomist, University of California (2006 and 2007), Larry Teuber, Professor, Plant Breeding and Agronomy and the Director of the California Foundation Seed Program (Teuber 2007b; Teuber and Fitzpatrick, 2007) and in the original Petition for Deregulation.

#### *5.4.1 Pollen-mediated gene flow into hay crops*

*Pollen-mediated gene flow* into hay crops is essentially zero (key references: Putnam 2006 and 2007; and, Teuber, 2007b). Experimentally, it is not possible to measure or detect pollen-mediated gene flow between adjacent hay fields because no seed is formed that may be evaluated (unless the forage field is intentionally neglected or mismanaged to the point of producing mature seed at which point it would technically be considered a seed-producing field *per se*). The best estimate of gene flow between neighboring forage fields is essentially zero.

In 2007, Putnam (2007) used probability estimates to calculate the risk of pollen-mediated gene flow between adjacent hay fields as follows: “...the probability that pollen from a neighboring GM hay field will contaminate a neighboring organic or otherwise GM-sensitive hay field is 0.0000025%, or 2.5 out of 1 million AP... these probabilities cannot be known with great certainty, and will be affected by individual environmental circumstances—however; this does

not change the validity of the argument. It would only change the probabilities from very, very, very, very low, to very, very, very low AP in hay crops.”

According to Putnam (2006), “Although gene transfer from one alfalfa hay field to another is theoretically possible, a range of environmental barriers make gene movement very unlikely,” (see figure 1 in Putnam 2006). Taking into account ordinary biological and cultural considerations, “the likelihood of AP occurring between hay fields becomes infinitely small, likely to be far less than 0.001% of field biomass even under high estimates of each of these probabilities. [...] The probabilities of gene transfer are estimated to be very low between alfalfa hay fields.”

Teuber (2007a) stated that, “Under hay production practices that prevail in California, I believe that both seed to hay and hay to hay transmission are highly unlikely.” California is always among the highest producers of hay and seed and it has a highly conducive climate for rapid seed development. Therefore, it may be construed that if the risk of gene flow into hay is highly unlikely in California, it is also highly unlikely elsewhere in the U.S.

#### *5.4.2 Seed admixtures*

Separate from pollen-mediated gene flow, there exists the potential for an AP-sensitive hay (or seed) grower to inadvertently plant conventional seed containing low levels of biotech traits to establish their AP-sensitive forage field. As in other organic and AP-sensitive crop production settings, trait-sensitive producers can choose to purchase seed that is of known genetic origin (e.g., certified varieties) and or purchase seed that has been pre-planting tested for the presence of GM trait(s). Seed sellers representing their product as organic or claiming other specialty qualities (e.g., “GM-free or GM-free”) should produce and source their products from identity preserved seed companies or growers. There are numerous producers and suppliers of organic and conventional alfalfa seed products so it is certain that conventional seed choices will remain available in the future. In order to produce high quality conventional and organic seeds, FGI and other U.S. seed companies contract with conventional or organic certified seed producers in the U.S. and globally. In addition, in adherence to the FGI Best Practices, FGI will produce and process all Roundup Ready alfalfa seeds under stringent seed handling procedures effective in mitigating the risk of seed admixtures.

#### *5.4.3 Volunteers*

Seedling recruitment from previous alfalfa seed or forage crops is also a possible source of rare seed-mediated gene flow into subsequent hay (or seed) fields. The following text was excerpted from Van Deynze et al. (2008):

##### ***“Volunteer seedlings”***

“Volunteer alfalfa can germinate from viable, hard remnant seeds left in or on the soil by a previous alfalfa crop cycle. Alfalfa grown for hay represents more than 99 percent of

U.S. alfalfa acreage so the potential for volunteer seed-mediated gene flow within hay fields will be considered first.

The potential for seedling volunteers to arise from a previous hay crop is exceptionally small or non-existent as it is determined by the same parameters as Hay-to-Hay gene flow, i.e. a viable seed must fall to the ground and germinate in the new stand.. The potential for gene flow via remnant seed volunteers to a subsequent alfalfa hay crop planted in the same field is even more remote because the remnant planting seeds would be three to six years old by the time the stand is terminated (see “Hard Seed” and “Autotoxicity”) Both are further circumvented by crop rotation. Most hay ground is rotated to a different species for two or more years before replanting alfalfa for hay. Therefore, hard remnant seeds will decompose during approximately seven years of seed aging, cropping activities and continuous exposure to the biota in the soil.

Hard seeds in alfalfa are defined as the seeds with a hard seed coat that do not imbibe water in a standard 72 hour laboratory germination test. Hard seed content for different seed lots of a single variety can be as high as 69% and as low as 14%, depending on where the seed was produced and the weather conditions during seed maturation (Bass et al., 1988). Undersander et al. (1993) planted various seed lots of the same variety wherein hard seed varied from 11% to 44%. At three locations in the Midwest, emergence was measured on a regular basis for 120 days. This data showed that differences in hard seed content in commercial seed lots did not significantly delay germination, and that, independent of hard seed percentage, virtually all of the viable seed germinated within the first 90 days. All viable hard seed germinated in the seeding year with no seed germinating the next year, even in the absence of any competition.

Alfalfa grown for seed production occurs on approximately 0.5% of the total acreage planted to alfalfa. The acreage is small compared to that for hay; however, the likelihood of volunteer seedling-mediated gene flow is somewhat greater. Virtually all of the commercial alfalfa seed is produced under irrigation in the western US. Although there is no directly comparable data from the West looking at seed germination rate and hard seed content, some recent data monitoring the number of volunteers after alfalfa seed production in the field is useful. Reisen (unpublished) monitored volunteer seedlings following non-chemical fall termination of a dozen alfalfa seed production fields in Idaho. These fields were either fallowed or rotated to one of six rotational crops wherein alfalfa volunteer seedlings could be counted and controlled. The number of volunteer seedlings per acre were counted several times each year, and summarized by quarter, over the 3-year period (figure V-9). Arias (unpublished), likewise monitored volunteer seedling emergence in three Texas seed fields that had been fall-terminated using herbicide and cultivation. These three fields were rotated to corn for the next three years. Arias observed an average of 25 volunteers per acre during the first summer and zero thereafter (figure V-9). More aggressive stand take-out of seed fields and prudent management strategies for broadleaf plants in the subsequent crops was demonstrated to be very effective in mitigating nearly all alfalfa seed production volunteers in subsequent crops.

**Figure V-9: Volunteer emergence by quarter in Idaho (Loc 1) and Texas (Loc 2) for three years after seed field take-out (mean count/A)**

Figure excerpted from Van Deynze et al., 2008

## 5.5 Coexistence and mitigation strategies for conventional, organic, export and other GM-sensitive conventional forage producers

Seed and hay industry methods exist for successful coexistence of conventional, organic, and Roundup Ready forage (and seed) market segments. Coexistence of conventional and Roundup Ready alfalfa is desirable and possible (Bradford, 2007; Putnam, 2006; Van Deynze, et al., 2008; NAFA, 2007). Roundup Ready seed producers are required to take mitigation and stewardship steps to preserve conventional seed and hay markets. Similarly, Roundup Ready forage producers are obligated to follow trait stewardship and coexistence programs required by their Monsanto licensure (see section E.6., below). The following section describes GM (and conventional) trait avoidance measures that GM-trait adverse forage growers can use to produce conventional forage to meet specifications for organic, export or other specialty market sectors.

### 5.5.1 Field establishment using conventional varieties

According to Putnam (2006), “The most important steps to ensure hay trait purity are selecting non-GM varieties using certified seed from reputable companies, testing this seed for adventitious presence before planting, and maintaining product identity.” It may be noted that in alfalfa, because it is a perennial crop, the seed choice decision is made only once during the multi-year life of the stand; therefore, as in all alfalfa production, selecting the appropriate variety and seed source is a long-lasting decision. Similar to other crops using the Roundup Ready trait, there are simple to use seed, leaf and hay trait testing kits for alfalfa (e.g., Strategic Diagnostics, Inc. and Envirologix, Inc.) and trait test service laboratories commercially available to the GM-sensitive buyers and sellers who wish to test for the presence of the Roundup Ready

trait (e.g., BioDiagnostics, Inc., GeneScan, Inc. Mid-West Seed Services, Inc., and, various state's seed certification programs). The Roundup Ready seed test kits and protocols have been validated by the manufactures and by an independent third-party tester using field-grown seed samples (Teuber et al., 2007b). AP sensitive hay (or seed) growers should use seeds of planting stockseed grown under certification as well as an identity preserved system for additional assurance of high seed purity. Identity preserved production services are available from independent local third-party certifiers such as those accredited by the National Organic Program, Association of Official Seed Certification Agencies (AOSCA) and or OECD programs.

### 5.5.2 *Management of pollinators and neighboring cultivated or feral alfalfa*

Pollinators serve no purpose for the production of forage, and, well-managed forage fields with few open blooms do not attract or support the nutritional needs of pollinating bees. GM-sensitive conventional or organic forage producers can mitigate the small potential for GM-trait cross-pollination by not placing or allowing others to place bee domiciles (hives) in or near their GM-sensitive conventional forage field and harvesting the forage prior to seed formation. This is the routine forage management practice so no special management will be needed by the GM-sensitive forage producer.

In certain low-input forage production settings (e.g., southeast U.S. or northern Plains States), a very low number of conventional or organic hay producers allow honey producers to place hive boxes in their alfalfa forage fields. In general, honeybees demonstrate a strong behavioral preference *against* foraging for nectar in alfalfa (seed or hay fields) therefore flowering weeds or other crop species are more important sources of honeybee nectar and pollen (Arnett, 2002; Pitts-Singer, 2007; Teuber, et al., 2005). Overall, honey production on alfalfa is a very uncommon forage grower practice in the U.S. and it results in very mature forage with very low forage quality or in some cases, the conventional field is grazed or is not harvested. Under the terms of the Monsanto Trait Stewardship License Agreement, forage producers are prohibited from placing bees in their Roundup Ready forage fields. A low frequency of *feral* solitary bee species may visit blooming alfalfa fields to collect pollen or nectar, but they would contribute to a very minor amount of pollen flow between forage, seed or feral alfalfa populations (Hammon et al. 2006).

Another exception within the conventional forage producer group is a small number of diversified farmers who, based on seasonal drought or immediate market prices (hay versus seed price), they may sometimes opt not to cut forage but instead produce a summer “catch crop” of seed on the “forage” field. In this way, their alfalfa field is converted to a temporary, non-certified or “common” conventional seed production field. Catch crop seed producers were previously discussed in the Petition (section VII, subsection B.). The potential for gene flow in non-certified conventional or organic seed production is discussed as a part of the seed production system, below. Under the terms of the Monsanto Trait Stewardship License Agreement, Roundup Ready forage producers are prohibited from harvesting any seed in their Roundup Ready forage fields and in geographies where common conventional alfalfa seed production occurs, as a precaution to mitigate pollen availability and facilitate peaceful coexistence, the Monsanto licensee must harvest the Roundup Ready field for forage not later than 10% bloom.

Because feral alfalfa may act as a potential bridge (conduit) for pollinators between non-isolated fields or into feral populations of alfalfa (St. Amand, et al. 2000), Putnam (2006) recommends that, “Prudent steps to prevent excess flowering or seed production during hay production will be beneficial to maintain coexistence of GM and non-GM alfalfa. [...] Controlling feral alfalfa is a prudent measure to prevent movement of genes between hay fields.” As discussed in the Petition, Feral alfalfa is not common in most forage-growing geographies and where it is present and in close proximity, flowering can be controlled through clipping or feral plants eliminated by identity preserved forage producers, (appendix V-4, letters from Weed Control Experts).

### *5.5.3 Harvest management*

Optimal forage harvest management involves cutting at or before 10% bloom, typically occurring approximately one week after first flower. This harvest schedule greatly reduces the potential time in which there can be synchronous flowering of the conventional hay field and any neighboring Roundup Ready hay or seed production field. By managing their forage harvest dates and crop maturity, the GM-sensitive conventional or organic forage producers can eliminate the potential for any seeds to form within their conventional forage field; whether the pollinations may have resulted from in-field or out-of-field pollen sources.

Sometimes forage producers struggle to cut their hay in a timely fashion due to rain, saturated soils, equipment breakdown, etc., or a forage field rapidly progresses to advanced maturity due to high temperature or drought stress. In delayed maturity harvest situations, viable seed may form within the hay canopy. For reasons explained in depth by Putnam (2006 and 2007), the risk of cross-pollination and dropped seed establishment in the AP-sensitive conventional hay field is “very very very low” (projected to be less than 2.5 seed per million).

### *5.5.4 Crop rotation/field history*

Alfalfa producers practice crop rotation between terminated alfalfa plantings to avoid a build up of pests and maximize soil nitrogen credits to non-legume rotational crops. Conventional forage producers wishing to avoid GM-traits may select fields without a prior history of GM variety use and or use pre-planting cultural and chemical controls and rotational crop choices appropriate to the elimination all alfalfa volunteers prior to planting the conventional alfalfa stand. Although “hard” alfalfa seeds may be viable for many years under dry laboratory conditions, in the field where moisture is present, extremely few or no hard seeds survive or successfully establish as volunteers within or outside of cultivation due to limited germling vigor, field biotic and abiotic decay processes (Undersander, 2005; Bass et al., 1988). Even when abundant mature seeds have been grown and dropped in the field (e.g., within or adjacent to a seed production field or its area of water drainage), two or four growing seasons without alfalfa are sufficient to mitigate remaining hard seed volunteers for the production of certified or foundation class alfalfa seeds, respectively (AOSCA, 2003). Therefore, GM-sensitive forage (or seed) producers can utilize traditional, reasonable crop rotation cycles and volunteer controls to mitigate the small potential for in-field volunteers from a previous alfalfa planting or mitigation of seeds that may have been moved by natural or irrigation water, wind or animals, etc.

#### *5.5.5 Identity preservation of conventional, organic or GM-sensitive hay lots*

Post-harvest mechanical co-mixing of forage lots is a separate, potential source of determinate (non viable) gene (detectable trait) flow between harvested hay lots, i.e., trait flow that is independent from seeds or living plant material. Identity preserved hay growers such as those producing conventional, export, weed-free, GM-free, and or organic hays can adapt their existing market-required hay lot identification processes to segregate, label, test and sell hay lots by cutting date, field and farm identification number. The available Roundup Ready trait hay test kits and hay lot sampling protocols have been validated by third-party testers using harvested hay field samples (Putnam, 2007; Woodward, 2006; Woodward, et al., 2006). As stated by Daniel Putnam (2006), “Organic growers already have a process by which they identify and document organic hay, so no greater paperwork burden would be generally required to deal with this situation”. For conventional hays, quality tested hay lots are likewise routinely identified and segregated (Putnam, 2004). According to Putnam (2006), prior to the advent of GM alfalfa, “Export and organic markets already require paperwork that identifies the lot, seller, and origin of hay, so a GM or non-GM label may be relatively simple for these marketers.”

#### *5.5.6 Equipment sanitation*

Contaminated equipment can be a source of physical co-mixing between dissimilar hay products (e.g., organic, conventional or GM-trait), cross-contamination between planting seed lots or it might transfer soil/stems that contains weed and or alfalfa seeds. Equipment sanitation is an effective, simple precaution that is highly effective and recognized as critical in all identity preserved production systems. Planters, cultivators and forage harvesters, processors, etc. may be cleaned before or after use to avoid unwanted residual debris or seed. In some situations, it is possible to designate that a piece of equipment may only be used in preplanned sequence or for certain types of products (e.g., organic fields only), so that the need for cleaning between product types is reduced or eliminated. It should be noted that equipment sanitation is useful to prevent the unintended dissemination of weeds, foreign materials and pests between fields so equipment sanitation is recommended and will remain important to product integrity irrespective of GM-trait sensitivity.

#### *5.5.7 Mitigation of negative impacts through prudent record keeping, planning and contractual agreements*

Complete and correct field and harvest records and advanced planning are recognized as critical to producing crops with consistent and predictable attributes. Producers of organic crops must maintain records and develop an organic crop production plan that satisfies National Organic Program Standards. Certifiers are available to document that minimum production standards were fulfilled. Similar use of records, planning and independent certification will assist those forage (or seed) growers who wish to avoid Roundup Ready or other GM-traits in fields, seeds or equipment.

*Contract stipulations regarding tolerance limits to GM traits:* To manage potential economic negative impacts of unwanted traits in hay, GM-sensitive, organic or other conventional hay

producers may use the effective gene/trait mitigation and avoidance practices discussed above which are based on sound science and successful co-existence models adopted in previous GM crop market channels and in use for specialty market alfalfa hays such as organic, certified weed-free or forage quality tested hay lots [see USDA-AMS Livestock and Seed Program (<http://www.ams.usda.gov/lsmnnpubs/hsum.htm>) web site for examples of by-feature hay lot identification strategies]. In addition, some of the potential negative impacts to sensitive producers may be avoided by careful consideration of voluntary contract specifications prior to signature on the agreement. Buyers and sellers alike, must read, understand and manage the GM-specific language that is offered to/by them in voluntary buyer-seller contracts. As in other crops where GM traits are in commercial use, forage (or seed) producers who agree to absolute zero-presence GM contracts could individually experience more negative impacts than producers using contracts with verifiable testing standards for GM trait presence/absence. During the initial deregulation period for Roundup Ready alfalfa (June 14, 2005 to May 12, 2007), several conventional alfalfa seed and hay producers implemented contracts that stated a greater-than-zero tolerance level (low-level presence threshold) for conventional alfalfa products [e.g., less than 0.5-1 percent trait threshold in conventional seed (McCaslin, 2007)]. Contract verbiage recommendations for GM-sensitive alfalfa forage contracts have been published by William Woodward, Extension Faculty, Washington State University (Woodward, 2006a and 2006b). Woodward has provided examples of recommended contract statements to adopt and statements to be avoided in conventional (specifically export) hay contracts. Woodward's hay industry guidance recommendations, are congruent with statements regarding the adventitious presence contract and labeling guidance positions of American Seed Trade Association (ASTA), Council for Agriculture Science and Technology (CAST) and the USDA National Organic Standards Program. Testing tools and statistical interpretation for GM trait tolerances are available on-line to help guide and inform members of the GM-sensitive hay (and seed) industries (e.g., see Woodward, 2006, CAST and ISTA web sites).

## 5.6 Coexistence strategies for producers of Roundup Ready alfalfa forage

All purchasers of Monsanto's Roundup Ready traited alfalfa seed are obligated to adhere to all terms of the Monsanto Trait Stewardship Agreement (MTA) which is a limited use license for the patented seeds. These important coexistence and trait stewardship program obligations and limitations are presented in the 2008 Monsanto Technology Use Guide (TUG) (Monsanto, 2007).

Alfalfa hay is planted in every state in the U.S. Intermingled alfalfa hay and alfalfa seed production only occurs in portions of a few western states which have the specific climate required for successful commercial production (figure V-1 and figure V-2, compare areas of overlap). Certified alfalfa seed production requires minimum isolation from alfalfa (hay/seed/feral) of any other variety (AOSCA, 2003). The isolation is inspected and verified by state seed certification organizations or, if organic, the planned buffer zone is verified by an accredited organic certifier. Although non-certified seed is not officially regulated or inspected, in areas where "common" seed production is intermingled with Roundup Ready forage production fields, the Roundup Ready alfalfa forage producer is required to harvest at or before 10% bloom (Monsanto Technology Use Guide and Monsanto Technology/Stewardship Agreement, 2008). This requirement is very effective in mitigating the pollen and pollinators in

Roundup Ready forage fields that might possibly travel to neighboring common alfalfa seed fields (e.g., Putnam, 2006).

## 5.7 Overview of Roundup Ready Alfalfa Seed Crop Management and Seed Industry Systems

All Roundup Ready alfalfa varieties are patent protected, AOSCA registered proprietary cultivars that are phenotypically and genetically identifiable due to the presence of the Roundup Ready gene. Trait licensing requirements and the presence of the unique gene insertion will offer previously unavailable tools for intellectual property protection (e.g., genetic fingerprinting of parent lines) and marketplace stewardship opportunities in alfalfa.

Forage Genetics is the exclusive Monsanto seed-producer-licensee for Roundup Ready alfalfa cultivars. Seed increase on any Roundup Ready alfalfa cultivar requires a special seed grower contract issued through Forage Genetics or one of its sub-licensees (to-date, December 16, 2007, there is only one sub licensee and the number is expected to remain small due to the small number of candidates).

All Roundup Ready seeds must be grown and sold by variety name (no common seed production is authorized). Each FGI Roundup Ready alfalfa seed grower and seed company is obligated to the terms of the Monsanto Trait Stewardship Agreement and Forage Genetics seed producer contract terms that require implementation of FGI Best Practices for Roundup Ready Trait Stewardship.

To maintain variety type, FGI Best Practices and official variety registration descriptions require seed growers to apply one application of Roundup agricultural herbicide per growing season and in accordance with State and Federal product registrations. There are separate labels for Roundup agricultural herbicides in forage versus seed production settings: one or more Roundup agricultural herbicide formulation is labeled in 50 or 13 states, for forage or seed, respectively. Roundup Ready cultivar seed production may only be legally grown in states where a Roundup agricultural herbicide label has been approved for seed crop production. As a part of the seed trait stewardship program and as a means to mitigate gene flow to occasional common conventional or potential organic seed producers, FGI and Monsanto have chosen not to contract for or to enable legal seed production of Roundup Ready alfalfa in some states where common seed production is most typical and or certified alfalfa variety production is very atypical (e.g., Kansas, South Dakota, North Dakota, Minnesota, and Nebraska). An outcome of the NAFA Coexistence workshop was that the steering committee agreed to facilitate the development of a binding Best Practices for Roundup Ready seed production document which was supported by all three of the genetic supplier member companies (Peaceful Coexistence: Creating a Strategy for Harmony Among GM, Organic and Conventional Alfalfa Producers, October 10, 2007, Denver, CO). These three current NAFA members represent approximately 90 percent of the U.S. proprietary cultivar conventional genetic supply capacity and 100 percent of the Roundup Ready seed producer companies. Terms of the Best Practices document will be publicly available information and it will be available from Forage Genetics and or the other Roundup Ready Seed Producers. Along with the genetic suppliers, state seed certification organizations will play a key role in coexistence monitoring and management. This agreement will help ensure mechanisms for peaceful coexistence among conventional, organic and GM alfalfa seed

producers and choice for growers to use organic, conventional and GM varieties. The Best Practices also stipulates that all Roundup Ready seed producers will respect local “conventional only” seed zones should they develop.

## 5.8 Overview of Alfalfa Industry Coexistence Systems Development

During 2000-2005, APHIS regulated studies were conducted using either introduced leafcutter bees as the primary pollinators (McCaslin et al., 2001), 2001 (Fitzpatrick et al., 2002; Fitzpatrick et al., 2003; Teuber and Fitzpatrick, 2007) or, introduced honeybees (Teuber et al., 2004 and 2005b). In all gene flow studies to date, in addition to the stocked pollinator, native and feral non-native bees were present at ambient levels so their potential contribution to gene flow under commercial conditions has been accounted for in the available data sets. In the 2006 growing season while Roundup Ready alfalfa was not APHIS regulated, FGI and public scientists conducted additional gene flow research studies (Teuber and Fitzpatrick, 2007; Hammon et al., 2006; Fitzpatrick et al., 2007b; Teuber et al., 2005a and 2007).

During 2006, FGI continued to implement and evaluate efficacy of its Best Practices for Trait Stewardship in Seed Production. Over 120 conventional FGI commercial seed lot samples were evaluated to ascertain the actual amount of gene flow between commercial-scale, Roundup Ready and conventional seed fields under leafcutter bee, honeybee or typical mixed-species pollination systems throughout key regions of the western U.S. These commercial seed lot data validated that the FGI Best Practices are effective in mitigating adventitious presence of Roundup Ready alfalfa pollen-flow to very low or non-detectable amounts: AP percentages were, in all lots, not detected or at levels less than would have been projected using the worst-case research trial study predictions (Fitzpatrick et al., 2007a and 2007b), thereby validating that the commercial seed trait stewardship program was achieving a key objective—mitigation of gene flow to conventional and organic seed producers.

There is a strong body of evidence to support that the comprehensive and collective Roundup Ready alfalfa trait licensing and stewardship programs implemented by Monsanto and FGI plus implementation of reasonable trait-avoidance quality control measures by GM-trait sensitive conventional producers are and will be effective in preserving market choices and allowing successful coexistence between Roundup Ready and conventional hay and forage producers; this includes those conventional producers growing seed or hay for export, organic or other GM-trait sensitive market niches. Over the past decade, the U.S. domestic and international agricultural seed and grain industries have a proven track record of developing and adopting coexistence mechanisms in the production and marketing of several other agricultural crops where GM-varieties are available.

The U.S. alfalfa industry has taken key steps toward coexistence and product differentiation. Some examples are:

- *AP tolerance, greater than zero*: During 2005-2007 growing seasons, certain alfalfa seed companies with GM-trait production sensitivities began to issue seed grower contracts with stated AP tolerances, e.g., “<1% GM trait” (McCaslin, 2007), thereby,

demonstrating that mainstream conventional seed companies are (were) shifting toward market coexistence and GM-trait tolerance in conventional seeds. Roundup Ready trait detection methods and commercial test services are readily available to help seed and hay producers, buyers and sellers support their company's quality assurance programs. A stated position of the American Seed Trade Association (ASTA, 2007) is that zero tolerance to gene flow of a commercially adopted trait (e.g., Roundup Ready alfalfa 2005-2007) is not an attainable or realistic goal for most producers in large scale U.S. production agriculture. There is an alfalfa industry consensus that a tolerance value greater than zero for GM traits should be developed and implemented (e.g., NAFA, 2007). A 0.5% AP tolerance for domestic use, non GM-sensitive seed, has been proposed by several NAFA members to be an attainable and effective tolerance goal (NAFA, Denver, CO, October 10, 2007).

- *Offering sale of GM-trait alfalfa varieties:* Although not necessarily producing the Roundup Ready seeds or breeding the varieties themselves, all four of the major U.S. seed genetic suppliers and seed production companies (Forage Genetics, Pioneer Hi-Bred, Dairyland Seeds and Cal/West Seeds) were Monsanto licensed and sold one or more Roundup Ready alfalfa varieties alongside of their own conventional and or organic seed product offerings. Roundup Ready alfalfa was sold by more than 20 seed brands all of which continued to offer conventional cultivar products.
- *Rapid market penetration:* During the 2005-2007 period of deregulation, approximately 300,000 and 18,000 acres of Roundup Ready alfalfa forage and seed, respectively, were grown with no substantiated cases of conventional forage or seed market disruption (McCaslin, 2007).
- *Value-added trait opportunity for domestic seed growers:* Roundup Ready alfalfa seed is only produced (and consumed) in the U.S. Therefore, U.S. seed producers of Roundup Ready alfalfa seed have had an exclusive value-added market opportunity wherein there is no foreign competition by lower-cost seed producers.
- *Seed industry cooperation towards peaceful coexistence:* The FGI Best Practices are effective in mitigating gene flow to conventional seed production to a very, very low level (Fitzpatrick et al., 2007b). Monsanto, FGI and Roundup Ready alfalfa licensees have implemented comprehensive trait stewardship policies and have worked proactively with state seed certification organizations to develop industry tools for coexistence and mitigate GM-trait gene flow to very, very low levels. Two examples of such industry cooperation are the California Alfalfa Industry Stakeholders Meeting hosted by the University of California-Davis Seed Biotechnology Center, on January 27, 2005 (UCDSBC, 2005) and the National Alfalfa and Forage Alliance's workshop on peaceful coexistence strategies held on October 10, 2007 in Denver, CO (NAFA, 2007). The NAFA coexistence workshop resulted in the joint authorship and development of five alfalfa industry consensus documents that will be available from the authors or from NAFA (<http://www.alfalfa.org>) with the following topics

1. Gene flow in Alfalfa: Biology, Mitigation and Potential Impact upon Production for GM-sensitive Markets (White Paper); Authors: A. Van Deynze, S. Fitzpatrick, B. Hammond, M. McCaslin, L. Teuber, D. Undersander and D. Putnam
2. Best Practices for Roundup Ready Alfalfa Seed Production; a binding consensus for all commercial producers of Roundup Ready alfalfa seed

3. Export hay market coexistence, risks and mitigation of gene flow
  4. Export seed market coexistence, risks and mitigation of gene flow
  5. Organic market coexistence, risks and mitigation of gene flow \
- *Independent monitoring and oversight of FGI seed stewardship practices:* FGI has used third-party inspection services to document its compliance with its Best Practices seed field isolation distance policies (e.g., Lowry, 2007). Crop Improvement Organizations have used this GM seed field location information to assist GM-sensitive seed producers in seed field isolation planning and their identity preserved process inspections.
  - *Validation of best practices for seed production:* FGI and NAFA Best Practices isolation requirements and stewardship during seed production have been evaluated and validated. Use of the Best Practices resulted in zero to very low levels of the Roundup Ready trait in conventional seed lots, e.g., 0.00 to 0.18 percent AP (Fitzpatrick et al., 2007a and 2007b; Miller, 2007).
  - *Seed company communication and low level AP:* In specific conventional seed lots, when detectable AP has been publicly claimed to have occurred outside of FGI contracted conventional seed lots (e.g., informal comments quoted from a 2006 Idaho Eastern Oregon Alfalfa Seed Grower meeting), if a percentage AP has been publicly claimed it has been at a very low level, i.e., “trace to 0.9 percent”—levels below the 1% contract tolerance in all relevant cases (McCaslin, 2007 declaration) and not in conflict with the up to 1% off-types allowed by varietal purity standards. FGI has worked cooperatively with other seed companies on a case-by-case basis to successfully resolve seed field proximity challenges (McCaslin, 2007).
  - *Growth of organic market sector:* For the past several years, the number of alfalfa forage acres certified as organic has increased (2005-2007) and likely flourished in-part due to the publicity surrounding the commercial use of the first GM-trait in alfalfa (Putnam, 2006; Putnam, 2007). Organic and identity preserved GM-free forage and seed products are new premium-priced, differentiated, and specialty market opportunities available to U.S. alfalfa producers. Demand for organic alfalfa is expected to grow for the next several years so that supply is sufficient to meet the growing market size of organic dairy and livestock producers.
  - *Increased awareness and education regarding seed quality issues and seed certification:* Especially for GM-sensitive market sectors like organic and export, there has been increased education and discussion about the importance of and value in using identity preserved production methods, planting certified variety seeds and benefits of enhanced quality control. It is anticipated that during 2008, AOSCA member agencies will begin to offer new inspection and certification services that exceed traditional seed certification standards and that are customized specifically for the identity preserved conventional, organic, export and GM alfalfa seed markets. The gene flow information has and is being used by state, national and international seed certification programs to review and if needed update certified seed production standards. Individual seed companies are also using the information to review current company policies. Information to support coexistence of diverse market sectors has been made available in numerous public, government, court, scientific society, seed grower, hay grower, industry stakeholder and

industry-wide presentations and much information is readily accessible to the public on searchable internet web sites or by contacting a state forage extension specialist.

## 5.9 Coexistence and mitigation strategies for conventional, organic and other GM-sensitive alfalfa seed producers

Key references are the in-press NAFA and CAST documents (2008) describing coexistence and mitigation of gene flow for organic and export producers.

### 5.9.1 *Isolation from unknown or dissimilar alfalfa varieties and field history (physical and temporal separation)*

GM-sensitive conventional and organic alfalfa seed producers wishing to produce a genetically pure seed crop may utilize AOSCA (2003), state seed certification program rules, and/or National Organic Program standards to physically and/or temporally genetically isolate their GM-trait sensitive production field. AOSCA programs stipulate standards for an appropriate physical isolation distance from other alfalfa pollen sources and NOP standards require that a buffer zone should be observed. Seed certification rules require a minimum crop rotation period and in-crop volunteer control (e.g., two or more years of field history without alfalfa cultivation). Typically, when genetic purity is desired, in-crop volunteers are controlled to ensure seed quality. Where a GM-trait sensitive conventional alfalfa seed field is grown in proximity to any other alfalfa, at a minimum, the AOSCA isolation requirements for certified seed production should be observed. The requirements are designed to ensure high genetic purity and minimize off-types (AOSCA, 2003). The seed producer may wish to utilize seed or organic certification inspection services to document that the grower's desired isolation and other available crop identity preserved protocols have been observed. The certified seed program rules, the Federal Seed Act and National Organic Program Standards all allow for a low frequency of genetic off-types in certified seeds; zero tolerance is not required. Individual conventional GM-trait sensitive seed producers may follow isolation or other protocols more stringent than program certification requirements so that unintended traits may be further avoided. Some state seed certification programs offer inspection services for enhanced, grower-defined identity-preserved programs intended to produce seeds of specialty quality (e.g., foundation generation or certified stockseed, low linoleic acid soy grains, certified organic, certified low-level GM products). Recently (July 24, 2007), the AOSCA alfalfa crop committee proposed a new identity preserved certification program designed specifically to enhance market coexistence opportunities and facilitate the segregated production of Roundup Ready and certified low/no-AP conventional alfalfa seeds lots (Larry Teuber, AOSCA Alfalfa Committee Chair).

In conformance with the NAFA and the FGI Best Practices for Seed Production Stewardship, Roundup Ready alfalfa seed production is currently planted with a minimum isolation distance of 900 ft, 1 mile and 3 miles from existing conventional seed production, for leafcutter bee, alkali bee and honey bee pollination, respectively (figure V-8). Field location and field size are reported to local state seed certifying agencies that inspect to determine that the minimum isolation requirement is met. This extraordinary isolation requirement is 5-95 times the current isolation requirement for conventional certified seed production. These science-based and highly precautionary FGI isolation guidelines for Roundup Ready alfalfa seed production were

established through open discussion among stakeholders, in forums organized by state crop improvement organizations (UCDSBC, 2005; Lowry, 2007; NAFA, 2007).

### *5.9.2 Stockseed genetic purity*

Conventional (and organic) alfalfa seed producers wishing to avoid GM-traits, inferior seed germination or vigor, weed seeds or organic program prohibited methods should plant high quality seeds of a known variety sourced from a reputable seed supplier. Prior to planting, the GM-sensitive conventional seed producer can require that an identity preserved seed lot sample be tested for the presence of the Roundup Ready (or other GM) trait. Similar to other crops using the Roundup Ready trait, there are simple to use seed, leaf and hay trait testing kits for alfalfa (e.g., Strategic Diagnostics, Inc. and Envirologix, Inc.), and trait test service laboratories commercially available to the GM-sensitive buyers and sellers who wish to test for the presence of the Roundup Ready trait (e.g., GeneScan, Inc.; Mid-West Seed Services, Inc., and, various state's seed certification programs). The Roundup Ready seed test kits and protocols have been validated by the manufactures and or by a third-party tester using field seed samples (Teuber et al., 2007b). Most of the U.S. seed crop is grown by variety name under contract with an alfalfa seed company who provides and defines the genetic quality of the planting stockseed. Therefore, because most alfalfa seed growers produce seed under a contract, most individual alfalfa seed growers do not self-determine which seed lot to use; the variety developer or seed company provides the grower with the seedstock. Seed companies that contract and provide stockseed to seed growers by variety name routinely test the stockseed for germination, purity, and key variety characteristics and GM-sensitive conventional producers have and will test seed lot samples for the presence of GM traits. The commercial issues associated with adventitious presence of GM-traits in seed have been extensively discussed with the global seed industry for more than a decade; the alfalfa seed industry has and will build coexistence and trait stewardship models using the experience gained in other crops enhanced using modern breeding methods (e.g., UCDSBC, 2005; NAFA, 2007).

Professional plant breeders and seed certification inspectors routinely monitor foundation seed stocks for off-types (e.g. flower color, plant stature, etc.) that are not characteristic for the described variety and breeders use simple conventional breeding approaches to proactively eliminate and manage against undesired off-types. These routine procedures for seedstock maintenance and quality control can effectively manage the rare occurrence low levels of biotech traits in conventional seedstock. In the event that conventional seedstock or breeder germplasm lines were suspected of containing adventitious presence of a biotech trait, the contamination can be excluded in parental lines using simple Roundup Ready trait/protein detection screening methods prior to pollination of the breeder generation. Tissues from candidate parent plants can be pooled or individually tested using the lateral flow strips designed specifically for fresh leaf tissues available from Strategic Diagnostics, Inc. and Envirologix, Inc. Any individual plants found to be trait positive would be excluded from the conventional parents prior to pollination of the breeder seed. Breeder seeds would then be grown using foundation or greater isolation to produce foundation seeds. Foundation seeds would be planted to produce commercial certified class seeds using certified class or greater isolation.

### 5.9.3 *Management of cultured pollinators*

Most conventional seed producers control the bee species, bee domicile field placement, bee stocking date(s) and bee stocking rate(s). Seed producers can mitigate (reduce) the potential for cross-pollination with outside fields through prudent cultured bee management, and, where summer temperature is not too high, they can opt for the use of leafcutter bees instead of other bee species because leafcutter bees tend to forage at shorter distance from their domicile. The majority of alfalfa seed producers add either leafcutter bees or honeybees to the seed field to synchronously and efficiently pollinate the crop. Conventional alfalfa seed has historically been grown using either cultured honeybees or leafcutter bees, in the Desert Southwest and Pacific Northwest, respectively. In the northern, central and southern Plains where a small proportion of the alfalfa seed is produced (and seed yield per acre is very low), the type of pollinators used is more variable: typically seed producers in these marginal production areas rely on feral and native bees. In certain niche geographies where suitable soil beds exist (e.g., southern Washington), permanent colonies of the ground-nesting alkali bee may contribute significantly to commercial alfalfa pollination (estimated to contribute 20% pollination for alfalfa fields proximal to an alkali bee bed); alkali bee pollination is often augmented by adding cultured leafcutter bees. GM-sensitive conventional seed producers can take further steps to mitigate cross-pollination with unknown alfalfa pollen by stocking the field with bees (to synchronously and quickly pollinate the field and make it less attractive to feral bees). They should stock freshly emerged young leafcutter bees and maintain them in the same field for the full pollination cycle (i.e., to keep them oriented to forage near the home hive).

### 5.10 Coexistence strategies for Roundup Ready alfalfa seed producers

Roundup Ready alfalfa seed growers and seed producing companies (“producers”) must be licensed by Forage Genetics and by Monsanto. The Roundup Ready seed producers, therefore, are obligated to follow all of the trait stewardship terms in their contracts and license agreements. Key features of the licensing agreements that will be important to seed marketplace coexistence are the requirements for implementation of all of the following:

- Seed field location and planting date; inspected by crop improvement
- Extraordinary, pollinator species-specific seed field isolation at planting (extraordinary pollinator-specific isolation will be 900 ft, 1 mile or 3 miles minimum for leafcutter, alkali or honeybees, respectively); inspected by crop improvement
- Seed field stand termination date; inspected by crop improvement
- Education and compliance auditing: FGI and Monsanto have implemented grower education and third-party auditing procedures to help insure awareness and compliance with license agreements.
- Authorized seed transfers only: All Roundup Ready seeds transferred only to the contracting company (no saved seeds, no transfer or sale to third parties). Any seed transfer requires licensure and associated stewardship.
- Product labeling/differentiation: Roundup Ready seed may not be legally sold without its variety name or into unlicensed or common seed channels. Processed Roundup Ready alfalfa seeds will be differentiated from conventional or

common alfalfa in that they will be coated with a distinct purple colorant and transferred in packages labeled “Roundup Ready Alfalfa”.

- Best Practices policies: Rigorous policies are science-based and market stakeholder-driven, and as such, the company (and or NAFA) may revise its Best Practices as new information is developed or as new coexistence consensus agreements or strategies are developed by the alfalfa industry (e.g., NAFA, 2007).

### 5.11 “GM-sensitive” alfalfa markets

The Roundup Ready technology would offer the technology-adopting alfalfa producers a new tool for broad-spectrum weed control throughout the life of the alfalfa stand. However, because the Roundup Ready varieties have been developed using a process of biotechnology, that is, they are genetically modified (“GM”) or genetically engineered (“GE”) certain market sectors (e.g., organic) and individual producers who object to GM traits *per se* will not want to use them and they will take steps to strictly avoid any detectable levels of GM in their products or on their farms. This has occurred in other crops. The stated GM-sensitivity of individual customers or markets varies from those having “zero tolerance”, “none detected”, “not more than X percent GM”, etc., and it varies among individual contracts and by importing country tolerance limits, if applicable. For purposes of the Roundup Ready market impacts analysis, “GM sensitive” is defined hereafter as the producers/customers that require that less than 0.5 % GM trait is present. Although certain buyer-seller agreements require it, zero presence is not statistically provable, it is not required to meet USDA National Organic Program (NOP) Standards, and it is unlikely to be feasible after large-scale commercialization of GM varieties (ASTA, 2007; see statements made by Mike Gumina in NASDA-PEW, 2006).

The organic and a portion of the U.S. agricultural export market channels are now averse and categorically closed (or nearly so) to essentially all traces of GM products, regardless of the crop, the commodity type, the trait or its regulatory approval status. In most of these markets there is no stated tolerance to GM trait presence, but international trade has continued in these crops. There have been GM AP tolerances—with conditions, established for food products in Australia (1%), Brazil (1%), the European Union (E.U.) (0.9%), Japan (5%) and Korea (3%) [see statements by M. Zumwinkle (NASDA-PEW, 2006)]. Various tolerance levels may be agreed to in buyer-seller contracts.

The development of identity preservation systems where growers produce a crop to meet certain market segments (i.e organic, conventional) is not specific to the Roundup Ready trait. The alfalfa market GM-sensitivity is highly subjective as is the case for certain other sales attributes in some cases (Putnam, 2005). In other crop species—and in alfalfa following the June, 2005, deregulation action for Roundup Ready Alfalfa, market segmentation has occurred to differentiate organic, conventional and GM-free products. Identity preserved market segments have grown even within conventional crop markets. U.S. market coexistence has also developed so as to serve the economic, trade, environmental and social interests of diverse alfalfa market sectors (NASDA-PEW, 2006; UCDSBC, 2005; NAFA, 2007).

Organic forage and other specialty crop markets are demonstrating an increasingly rapid growth rate (e.g., 17 percent per year) despite, or perhaps in-part, because of increased organic food consumer awareness of biotechnology use in crops (Putnam, 2006). Based on the development of coexistence strategies and overall strong organic market trends, although individual organic hay producers may need to take new steps to avoid the unwanted presence/detection of Roundup Ready or other future GM alfalfa varieties, the introduction of Roundup Ready alfalfa and the likely public discussion surrounding it, may result in increased organic market demand and expanded opportunities for existing and new organic hay growers.

## 5.12 Details of key pollen-mediated gene flow studies

In studies using the Roundup Ready gene, the pollen source plot was planted to Roundup Ready alfalfa that contained a *cp4-epsps* transgene marker, the pollen trap (“sink”) plots were planted to conventional alfalfa over a range of isolation distances. Cultured bees were introduced to the test site following typical seed grower practice for each region. Studies were conducted in the Pacific Northwest and in California where leafcutter bees or honeybees, respectively, were introduced. Gene flow from source to trap plots was measured by evaluating the trap plot seed or seedlings for the presence/absence of the source plot pollen marker in a bioassay (i.e., % trap seed expressing glyphosate herbicide tolerance). Observed means were used to calculate pollen-mediated gene flow decay curve equations. Additional pollinator and gene flow studies are in progress to help validate Best Practices and add new information to that already available.

These data demonstrate that pollen-mediated gene flow diminishes significantly with increasing distance from the source, cultured bee species differ in their potential to mediate gene flow at a given isolation distance (figure V-8) and that smaller fields tend to have higher rates of gene inflow compared to larger fields. The data has been used as part of the scientific foundation in the development of the Best Practices for Seed Production.

Van Deynze et al. (2008) have reviewed the studies available to date for alfalfa gene flow between hay, seed and feral settings.

### 5.12.1 Quantity of seed-to-seed field gene flow under leafcutter bee pollination; key reference Fitzpatrick, et al., 2003

Gene flow data for leafcutter bees is presented in figure V-6 and has been summarized (Fitzpatrick et al., 2003). No gene flow (0.0000%) was detected at 2000 ft in 2000, and in 2002, only 1/30,000 seed was found to carry the pollen marker when isolation was ½ mile (2640 ft). Gene flow was not detected at ¾ or 1 mile isolation distances in this study. Observed gene flow for leafcutter bees ( $Y_{obs}$ ) is described by the equation,  $Y_{obs} = (1 \times 10^{10}) (X^{-3.6262})$ ,  $R^2 = 0.9391$ ; and, the upper bound of the 99.9% confidence interval for gene flow,  $Y_{CI}$  is calculated as,  $Y_{CI} = (4 \times 10^6)(X^{-2.3673})$ ,  $R^2 = 0.9728$ .

It is interesting to note that the amount of pollen-mediated gene flow in alfalfa (an insect-pollinated crop), as observed 2000-2002, approximates that observed for corn (a wind-pollinated crop). For instance, in a study conducted by Haskell and Dow (1951), out-crossing in corn was 2.33, 0.48 and 0.20% for plants located 125, 300 and 500 m from source plants, respectively.

*5.12.2 Quantity of seed-to-seed field gene flow under honey bee pollination; key references Teuber et al., 2004, 2005a, 2005b and 2007b*

In 2003, at 900 ft, honey bee-mediated gene flow was 1.49% and it decreased linearly to 0.20% near 5,000 ft [ $Y_{\text{obs}} = -0.0003x + 1.8529$  ( $R^2=0.98$ )]. Gene flow continued to decline out to 2.53 miles where it was detected at a very low but detectable frequency ( $<0.06\%$ ). Gene flow from 900 ft to 2.53 miles with honey bees was described by the decay equation  $Y_{\text{obs}} = -1E-12x^3 + 5E-08x^2 - 0.0005x + 1.9908$  ( $R^2=0.98$ ). Gene flow to the west and the east trap plots was not significantly different.

Honeybee pollination dynamics in alfalfa are the subject of an in-progress project (Teuber, et al., 2005a and 2007b) which has been cooperatively funded by USDA-CSREES, University of California and FGI. Preliminary data was reported in 2007 (Teuber et al., 2007b). Preliminary data from the 2006 crop year were similar to those generated in 2003 (previous paragraph). Traps at 1 mile with bridged isolation had similar gene flow to those at 1 mile with true isolation.

At 1 mile, gene flow between the large commercial fields was approximately 0.1% overall. At 3 miles it was approximately 0.03% and it was not detected at 5 miles (Teuber et al., 2007b)

*5.12.3 Quantity of seed-to-seed field gene flow between commercial seed grower fields and validation of the FGI Best Practices; key reference Fitzpatrick et al., 2007a and b*

In 2006-07, Forage Genetics International (FGI) implemented an internal seed quality assurance program to monitor and validate efficacy of the FGI Best Practices for Roundup Ready Trait Stewardship during Seed Production (“FGI Best Practices”). This was the first year of widespread commercial Roundup Ready alfalfa seed production in the United States.

Conventional alfalfa seed lots grown and/or processed in proximity of Roundup Ready alfalfa seed in 2006 and 2007 were tested for adventitious presence (AP) of the Roundup Ready trait. The data showed that AP of the Roundup Ready trait in FGI conventional seed lots occurred infrequently and, in all cases if detected, was at a very low level—0.004 to 0.180%. This level was well within the company’s goal of  $<0.5\%$  AP and below values predicted based on “worst-case” research models developed using smaller field sizes. This large-scale commercial validation of FGI Best Practices helps support research-based isolation standards and demonstrates the effective implementation of FGI quality control programs at both the grower and processor level. FGI believes this also demonstrates that reasonable tools are available and are being used by seed producers to allow successful coexistence within and between diverse alfalfa seed market sectors and preserve conventional seed and hay market choices.

The large-scale commercial validation also helps put in perspective the minimum incremental risk associated with potential “real world” concerns about pollination from wild pollinators, extraordinary pollen flow *via* wind-driven pollinator movement, and contamination through physical mixtures of seed in harvesting and/or seed processing.

#### *5.12.4 Quantity of hay-to-seed field gene flow under leafcutter and honeybee pollination of the seed field; key reference Teuber and Fitzpatrick, 2007*

Hay-to-seed field pollen-mediated gene flow measurements have been conducted in field studies in which effective gene flow was measured from a Roundup Ready hay field gene source to conventional seed production field pollen-traps plots. The two studies used the Roundup Ready trait as a sensitive pollen marker tool. Teuber and Fitzpatrick (2007) summarized both of the hay-to-seed gene flow data wherein overly mature hay fields were intentionally grown near to alfalfa seed field plots pollinated using bees. Data from the first study conducted in 2000 used trap seed production plots pollinated by leafcutter bees growing near to a hay plot not harvested until 50% bloom (i.e., five times the recommended forage harvest stage of 10% bloom); this study was described within Petition appendix 5. Additional hay-to-seed study data from the University of California were generated in 2006 using honeybees as pollinators on the seed plots and the hay field gene source reached the 20% bloom stage twice during the seed pollination period; again simulating sub-optimal harvest timing (Teuber and Fitzpatrick, 2007). The combined data are presented in figure V-6.

Bees were applied to pollinate the seed fields in these studies and during the midsummer pollination period the hay field plots were intentionally allowed to flower more extensively than is typical for forage. Therefore, the hay field gene sources were representative of delayed-stage cutting or poorly managed hay fields growing close to a seed field. Under these conditions, gene flow into the seed field was very low (0.2-0.3%) at 150-300 ft and, it was rarely detected (0.00 to 0.05%) at distances greater than 350 ft. The pollen-mediated gene flow decay curve from mature standing hay to nearby seed fields for the two combined study sets is:  $y = -0.1844 \ln(x) + 1.1778$ ,  $R^2=0.72$ .

#### *5.12.5 Feral alfalfa gene flow to/from commercial seed fields*

In geographies where alfalfa is cultivated, feral and neglected cultivated alfalfa populations exist. In some geographic areas feral alfalfa plants have resulted from intentional plantings in roadsides, rangelands or wildlife areas; in other cases feral populations were likely initiated from dropped alfalfa seeds (Petition section VII. E.). Potential for long-distance gene flow into unmanaged, seed-bearing feral alfalfa plants was studied using several marker gene systems described in the sub sections below.

##### *5.12.5.1 Quantity of gene flow from concentrated commercial scale seed fields to feral alfalfa plants; key reference Hammon, et al. (2006)*

Hammon et al. (2006) conducted a survey of the pollinator species present and the gene flow potential into feral and intentionally neglected (non-harvested) alfalfa plants growing amongst and nearby a cluster of commercial-scale seed fields producing Roundup Ready alfalfa varieties under contract in western Colorado. In 2006, when the trap (sentinel) plant seed samples were collected, the Roundup Ready gene source fields were in their third seed production year and were approximately 900 acres cumulatively. The seed fields were predominately pollinated using cultured leafcutter bees with some additional pollination mediated by local populations of honeybees, alkali bees and nine other non-cultured bee species documented in site survey collections. Conventional and Roundup Ready alfalfa forage fields growing in the vicinity were

cut at early flower and were not a source of pollen for the trap plants. There were no known conventional alfalfa seed fields growing elsewhere within western Colorado (> 50 miles isolation, minimum); therefore, other than the pollen from small groups of neighboring conventional trap plants or brief episodes of forage field flowering, the Roundup Ready seed fields were the sole source of alfalfa pollen for the past three years. In mid summer (July-August), seed collections were made at 23 trap plant sites; ten of the sites were sampled a second time in September for a total of 33 samples. Trap plants were separated 0 to 1.7 mile distance from the nearest Roundup Ready field edge (median sampling distance 0.51 miles). Seed was evaluated in a greenhouse seedling glyphosate tolerance bioassay. Under these sustained, commercial (extremely isolated) seed production conditions that conformed to the FGI Best Practices for the Roundup Ready seed production, the percentage of gene flow to the small clusters of feral/uncut plants ranged from 0 to 9.5 with the median and mean, 1.06 and 1.68 percent, respectively. The raw data from this study have been graphically presented as figure V-9. The researchers determined that honeybees and bumble bees were more likely than alkali bees to have effected pollination at distances greater than 1 mile from the seed fields. Due to proportion, scale, pollen competition and proximity effects—and a professional seed grower's ability to control feral alfalfa in many situations, it is very unlikely that the scattered, feral, cross-pollinated seeds would result in a detectable trait flow into subsequent years' conventional seed crops. Conventional seed growers sensitive to off-types or low levels of GM traits can actively clip or eliminate most nearby hay and feral alfalfa plants during the pollination period. Even if a low to moderate level of a GM trait is present in feral alfalfa populations, the amount of pollen available from the feral plants for bee transport into a conventional seed field will be extremely little relative to the vast amount of pollen produced within the commercial seed field.

#### 5.12.5.2 Risk of gene flow from commercial scale mature hay and seed fields to simulated feral alfalfa plants; key reference St. Amand et al., 2000

In the 1990's St. Amand et al. (2000) used a rare, naturally occurring genetic marker trait to estimate the maximum distance of pollen-mediated gene flow from late maturity-stage hay or seed production fields to simulated and natural feral alfalfa pollen trap plants. They utilized two different native marker gene techniques with three study objectives, specifically, the measurement of pollen-mediated gene flow: 1) from large commercial fields to sparsely planted roadside alfalfa, 2) within seed fields; and, 3) among feral alfalfa plants.

The pollen traps (1 m<sup>2</sup> each) contained a single genetic clone planted along a roadside vector. The small plots were left unclipped so as to simulate feral, non-isolated, incrementally spaced plants and allowed to ripen seed. There was evidence of cross-pollination of the clonal plants at 1000 meters and gene flow declined with increasing distance from the commercial fields. Assuming the clone genotype used was representative of alfalfa, all of the trap plants were self-incompatible (they would not successfully self pollinate or pollinate with other members of the same clone). This situation would have acted to artificially select against local pollen sources and select toward pollen carried from only the large fields, thereby, creating a setting to measure worst-case gene flow. St. Amand et al. (2000) determined that within-seed-field pollen-mediated gene flow could not be detected more than 4 meters from the pollen source plants, demonstrating that pollen from rarer genotypes is diluted by or possibly occluded by pollen subsequently

collected from surrounding plants in natural (heterogeneous) alfalfa populations. Therefore, in part, the potential amount or rate of realized long-distance gene flow into isolated feral populations will be mitigated by the local abundance of compatible genotypes at shorter distances if they occur.

#### 5.12.5.3 Isolation and field size

For the second and third study objectives, St. Amand et al. (2000) used two marker systems, the GS marker and a RAPD marker, to measure gene flow to unclipped ramets of a single, marker-free, genetic clone planted as twelve  $1\text{ m}^2$  pollen traps along a roadside at each of four locations. Small plots have a higher percentage of out-crossing versus larger fields (AOSCA, 2003) so the  $1\text{ m}^2$  plots would likely demonstrate extreme, worst-case gene flow potential. The pollen traps, intended to simulate dispersed feral alfalfa, were distributed along a single vector at each location at increasing intervals from each of the pollen sources (i.e., 0, 20, 40, 60, 80, 100, 200, 300, 400, 500, 750 and 1000 m distance). Source fields were managed either for seed or for hay production and were considered either commercial-scale (ca. 0.13 ha or 1.74 ha, for seed or hay, respectively) or research-scale ( $2\text{ m}^2$  for both seed and hay). The RAPD or GS markers were used as the pollen-tracking system for the commercial- or research-scale plots, respectively. Plots were located in the states of Washington and Kansas. The small and large seed-production plots in Washington were stocked with leafcutter bees, while all other plots relied on natural populations of native and or feral bees for pollination.

Data indicated that pollen flow from research plots was minimal, with 1% to 2% flow at 0 to 100 m and no flow was detected at distances greater than 200 m. These data would support the conclusion that 200 m (640 ft) isolation zone without border crop would mitigate pollen outflow from small plots and or into larger fields from small groups of neighboring feral alfalfa potentially containing a GM trait.

Gene flow from the four large fields to the very small ( $1\text{ m}^2$ ) pollen traps was notably higher, with 25% to 35% out-crossing measured at 1000 m. Data are presented for percent out-crossing, but the gross number of seed produced on each trap or trap plant (the sample size) was not reported. In other words, if few seeds were produced a very low number of outcrosses would equal 25% (e.g., 10/40), whereas, if normal seed set occurred, numerous outcrosses and multiple bee visits would have been necessary for 25% out-crossing (e.g., 100/400). The number of seed produced on the trap plants would be important for direct comparison of the clone of artificial feral plants to naturally occurring feral plants. Plants within and among small traps were of the same genotype (genetic clone), which was likely, self-incompatible to some degree. Therefore, the plants within a trap were unlikely to form seed with any plant *except* one whose pollen was carried from the source field. Therefore, interpretation of this data is not straightforward. While use of the clonal-trap is an appropriate technique to measure the maximum distance of potential pollen flow, it may result in artificially high estimates for gene inflow to natural (non-clonal) feral alfalfa populations. It should be assumed that the naturally occurring out-crossing mechanism prevalent in cultivated alfalfa is also prevalent in feral alfalfa populations. Therefore, the potential for self-incompatibility among the trap clone ramets (nearest neighbors) may have acted to select for pollen carried from non-genetically related individuals. Thus, the use of the clones may have artificially skewed the out-crossing frequency toward long-distance pollen sources relative to what may have been found if the trap plants had been cross-compatible

with each other (nearer sources) as is found in nature. In a diverse, heterogeneous, natural, feral population, there would be no bias for or against any source of non-self pollen and proportionately more progeny would trace to pollen carried shorter distances.

Other factors that may have enhanced flow to the very small clonal trap plots include the relative attractiveness of the plants with respect to other plants along the roadsides, small plot size and the close proximity of the traps. First, the close proximity and unidirectional, regular placement of the twelve trap plots may have influenced bee movement by forming a highly attractive, pollinator-conduit or bridge from one trap to the next. It is important to note that the relatively high frequency of out-crossing reported at 1000 m took place at the distal end of the regularly spaced, unidirectional trap plots. Although the findings may be relevant to gene flow bridging potential among (self incompatible) high-density feral populations, it would be inappropriate to apply the findings to long-distance flow with 1000 m of true isolation from the nearest alfalfa pollen source (e.g., between 1000 m isolated seed fields and or feral patches). Secondly, the trap plants were not clipped or managed in any way that would have made the twelve 1 m<sup>2</sup> areas less attractive to bees and this would simulate feral alfalfa only if it were growing in completely unmanaged or unmanageable roadsides or wild areas in proximity to GM-sensitive seed producers. In many conventional seed production situations, alfalfa seed growers can and do take effective steps and precautions to mitigate feral alfalfa and feral alfalfa pollen (Kendrick et al., 2005). It is also likely that after they transplanted the trap ramets, St. Amand et al. took steps to irrigate them, control weed competition within the trap plots, and may have otherwise encouraged the growth of the trap plants, making them cultivated rather than feral (entirely unmanaged) *per se*.

#### 5.12.5.4 Effects of borders and potential for short-distance or within-field seed field gene flow

St. Amand et al. used a naturally occurring variant of the alfalfa glutamine synthase (GS) gene as a marker to monitor within seed field gene flow from marked source plants to surrounding plants not containing the variant gene. Minor gene flow (0.2%) was detected 4 m or less from the 1 m<sup>2</sup> (non-replicated) source plot and zero gene flow was detected greater than 4 m from the source plants. The authors discuss that these results would indicate that pollen traps or borders might be effective to mitigate alfalfa pollen flow. It should be noted that in this study, the area covered by the pollen trap plants from which +GS seed was harvested (i.e., the non-marked alfalfa border plants located  $\leq$  6 m from the edge of the 1 m<sup>2</sup> gene source plot) was 134 times greater than the area occupied by the single block of gene source plants—a ratio that would be unmanageable for commercial alfalfa seed or forage production. Same-species border crops would be problematic for regulated and/or commercial alfalfa seed fields where genetic purity of the target seed product is of central concern, i.e., the use of a non-transgenic synthetic alfalfa variety to surround a Roundup Ready seed field would reduce trait purity, reduce varietal purity and preclude varietal certification because spatial isolation standards would not be met. Non-alfalfa borders may have incompatible agronomic management and/or irrigation requirements when grown in the same field with alfalfa seed production which would impact the crop's potential efficacy as a pollen trap. Additionally, because alfalfa is not a preferred source of pollen for pollen-collecting bees (Arnett, 2002) a non-alfalfa border species might be counter-productive in reducing gene

flow, because that crop may be more attractive to bees than the alfalfa which it surrounds. This could reduce pollinator activity on the alfalfa and/or unintentionally attract more rove or scout bees from distant colonies than the non-bordered alfalfa alone would attract and inadvertently result in longer-distance pollen-mediated gene flow. Another challenge would be managing species purity during seed harvest and cleaning. If seed from the border species commingled with the alfalfa seed product, seed cleaning costs would increase or, if the border crop seeds were very difficult to segregate from the alfalfa seed, even a slight decrease in species purity would significantly impair the alfalfa seed's value or marketability. For example, the presence of other small-seeded legume seeds, such as birdsfoot trefoil or red clover, negatively impacts alfalfa seed lot species purity. In significant quantities, it will prevent alfalfa seed lot certification and decrease the alfalfa seed lot's value.

## **6.0 Alfalfa in Non-Cultivated Lands (Existing Environmental Setting): Non-Agricultural lands where alfalfa may be present**

Alfalfa is a widely adapted plant that has been introduced and grown extensively throughout the U.S. and occasionally, plants may be established outside of cultivation. It is known that feral alfalfa populations exist sparsely throughout the United States. In the Petition data were presented to APHIS documenting that alfalfa survives to a small extent outside of cultivation, and providing an estimate of the extent of feral populations in the U.S. (see Petition sections VII.E., VII.F. and appendix V-4).

Recently, feral alfalfa is discussed by Van Deynze et al. (2008):

“Feral plants are crop plants that grow and reproduce outside of cultivation. Feral alfalfa plants can sometimes be found on road edges, in fence lines and in abandoned fields. In the US, feral alfalfa populations have occurred through unintentional plantings of cultivated varieties (“escapes” from cultivation) or, in some cases, they originated from intentional planting of the abandoned fields, roadsides or marginal lands. Feral alfalfa occurs at very low density and scale relative to cultivated alfalfa grown for seed or hay. Biogeographic survey data from six states indicates that for most agricultural areas feral alfalfa plants do not occur or they are sparse (Kendrick et al., 2005). In a 2001/2002 multi-state survey, feral plants were found as dispersed plants or patches within 1.25 miles (2 km) of cultivated alfalfa at only 22% of the survey sites (Kendrick et al., 2005). Feral alfalfa plants are sometimes managed on roadsides by clipping, either with hay being harvested or simply left on the ground along with the other roadside vegetation. Feral plants are sometimes completely unmanaged and given adequate moisture and timely presence of pollinators, can flower and set seed. Feral plants are susceptible to the environmental (e.g. drought in the irrigated West) and insect (e.g. Lygus bugs in the West and potato leafhopper in the East) stresses common to the local area. Although alfalfa was introduced to North America more than 200 years ago, it is not considered weedy, noxious or invasive in cultivated or feral settings.”

This statement, that alfalfa “is not considered weedy, noxious or invasive in cultivated or feral settings” is additionally supported statements submitted by several experts during the 2005

USDA public comment period [e.g., USDA docket 04-085-1, comments by Undersander #519 (Wisconsin), Doll #505 (Wisconsin), Murray #485 (Oklahoma), Beuselinck #501 (USDA-ARS Missouri), Whitesides # (Utah), Miller #502 (Wyoming), Howatt #510 (North Dakota), et al.].

The biogeographical survey data of Kendrick, et al. (2005) were used to assess the potential for gene flow from cultivated to feral alfalfa populations. In the survey, six states were selected representing major alfalfa production states in the U.S. The states surveyed were California, Idaho, Pennsylvania, South Dakota, Washington and Wisconsin. A total of 940 roadside sites were surveyed (500 M<sup>2</sup>/site). At approximately 22% of the sites, feral populations were located within 2000 meters of cultivated alfalfa. On average, alfalfa occupied <3% of the area surveyed. The results from this survey likely are representative of other states in the U.S. where alfalfa is produced for seed or forage. It is reasonable to assume that feral alfalfa populations also exist to a minor extent in other locations where alfalfa hay or seed is produced, or seeds are spilled during transportation or processing. The occurrence of feral alfalfa near seed-production sites was less than those observed where forage was produced; this may be because of the importance that seed producers place on maintaining isolation during seed production to ensure genetic purity of alfalfa varieties. Frequently, alfalfa exists outside of cultivation in abandoned and relegated fields or sown rangelands: i.e., the founder seeds for these populations were not recruited from feral or natural sowing and they were not transported by wildlife, but rather were initiated by human intentions and not since targeted for control.

## **Appendix V-2. Stewardship Program for Gene Flow Management in Roundup Ready® Alfalfa Production**

Monsanto and Forage Genetics International (FGI) have jointly developed Roundup Ready® alfalfa for commercial forage production in the United States. Prior to and after the introduction of Roundup Ready alfalfa (RRA) to U.S. alfalfa producers, Monsanto and FGI developed a stewardship plan that included securing regulatory approvals in key U.S. alfalfa hay export markets, implementation of hay and seed production practices designed to facilitate co-existence of both Roundup Ready and conventional alfalfa hay and seed<sup>1,2,3</sup> and a commitment to continued dialogue with alfalfa forage and seed producers.

### **1.0 Key Elements of Traits Stewardship**

#### **1.1 Licensing, contracting and pesticide registration**

Under terms of the Monsanto Technology/Stewardship Agreement (MTA) RRA may only be used to produce forage for feed uses. Seed production of RRA requires a specific contract from FGI or an FGI authorized FGI seed contractor. FGI is the sole Monsanto licensed seed producer. Although Roundup herbicide is broadly registered for RRA forage production purposes in the U.S., Roundup herbicide is labeled for seed production purposes in only certain states. Unregistered pesticide use and unlicensed commercial harvest, sale or uses of patent protected seed are violations of state and federal laws.

#### **1.2 Seed channel management**

All RRA seed is packaged with a unique purple seed coating and “Roundup Ready alfalfa” seed-bag labeling. RRA seed will only be sold by variety name. All seed purchasers, dealers, distributors, producers and processors of Roundup Ready seed must be licensed by Monsanto and agree to trait stewardship appropriate to their activities.

#### **1.3 Industry tools**

To support buyer-seller agreements that may stipulate conditions for biotech trait status, simple to use trait detection strips are available for alfalfa seed and hay product use (e.g., Strategic Diagnostics, Inc., Envirologix, Inc.).

#### **1.4 Mitigation of Pollen-Mediation GMNE Flow**

Gene flow between populations is a natural occurrence in all crops. Alfalfa requires cross-pollination by certain bee species; it is not wind pollinated. In alfalfa, the potential for Roundup Ready gene flow between fields is significantly constrained (limited) by crop and pollinator biology, typical alfalfa grower

---

® ROUNDUP READY AND ROUNDUP ARE REGISTERED TRADEMARKS OF MONSANTO TECHNOLOGY LLC

practices, and numerous additional grower practices required in the Monsanto license for forage growers and Forage Genetics best practices for contracted RRA seed growers as follows.

#### *1.4.1 Hay-to-hay field gene flow*

In alfalfa, forage producers cut hay at regular intervals prior to or near early bloom for optimum forage quality and yield. Pollinators are not attracted to non-flowering, vegetative alfalfa fields. The potential for pollen-mediated hay-to-hay field gene flow has been thoroughly discussed in a recent University of California publication<sup>4</sup> wherein it is stated that, "...the likelihood of AP [adventitious presence] occurring between hay fields becomes infinitely small, likely to be far less than 0.001% of field biomass even under high estimates. ...The combination of frequent harvests, lack of significant flowering, lack of significant seed production, and the highly competitive and allelopathic nature of alfalfa that prevents ready germination of alfalfa seeds in existing fields should prevent most if not all gene transfer".

#### *1.4.2 Hay-to-seed field gene flow*

Certified alfalfa seed must be produced using production methods and isolation defined and inspected by state seed certification organizations or an accredited organic certifier. Non-certified seed is not officially regulated. Seed producers and regulators recognize that genetic purity of the seed is related to physical isolation between the seed field and outside sources of pollen. For reasons explained above, due to sparse and short-term flowering, Roundup Ready forage fields are an unlikely source of pollen or pollinators. Hay-to-seed gene flow research has been conducted and data is publicly available<sup>1,2</sup>. Bees were applied to pollinate the seed fields in these studies, and, during the midsummer pollination period, the hay field plots were intentionally allowed to flower more extensively than is typical for forage: i.e., 50% bloom in 2000<sup>1,2</sup> and 20% bloom in 2006. Therefore, the hay field gene sources were representative of delayed or poorly managed hay fields growing close to a seed field. Under these conditions, gene flow into the seed field was very low (0.2%) at 150-300 ft and, it was rarely detected (0.00 to 0.05%) at distances greater than 350 ft. In contrast, forage producers who plant Roundup Ready Alfalfa seed will cut hay aggressively to manage for optimum forage quality and minimize the number of open flowers on the standing hay. In the western U.S. where hay and seed are both produced, licensees must identify the exact field location where Roundup Ready alfalfa seed will be planted. RRA forage growers will be monitored for compliance to license terms. Conventional seed producers can use reasonable seed field isolation distances from neighboring alfalfa fields and certified identity preserved best management practices (such as organic certification) to produce seed with little or no adventitious presence of traits from hay fields.

#### *1.4.3 Seed-to-seed field gene flow*

Certified alfalfa seed must be produced using production methods and isolation defined and inspected by state seed certification organizations or an accredited organic certifier. Non-certified seed is not officially regulated. Forage Genetics requires that all contracted RRA seed growers and conditioners follow FGI best practices policies for Roundup Ready trait stewardship. These best practices have been implemented to maintain high seed quality in FGI seeds; are based on industry experience and gene flow research data; and, they are effective strategies for assuring seed and hay industry market coexistence. It is well documented that isolation is one of the effective measures to mitigate pollen flow to very low levels<sup>1,2,5,6</sup> and that bee species differ in their potential to effect gene flow<sup>1,2,5,6,7</sup>. FGI and its contractors use process-based best practices that are modeled on the principles of AOSCA Foundation Class alfalfa seed production standards and crop identity preservation. Likewise, other producers of conventional and or specialty quality alfalfa seeds independently implement various production strategies to ensure their company's product quality claims. Research data is available to the industry so that other seed producers can use the information to manage seed quality<sup>2,5,6</sup>.

FGI Best Practices for RRA seed producers include: (1) All RRA seed is produced exclusively the U.S. using AOSCA and/or OECD certification standards. (2) At planting, all RRA seed fields respect a foundation isolation distance (or greater) to existing conventional seed fields: RRA eligible fields have 900 ft, 1 mile or 3 miles isolation for leafcutter bees, alkali bees or honeybees, respectively. (3) Seed growers must follow FGI's strict equipment sanitation, pollinator management and seed handling requirements. And, (4) the planting date, location, field size, variety name and termination date for all RRA seed production fields are reported to and inspected by the state's certifying organizations to facilitate the industry's management of field history and seed field isolation information.

**Appendix W. Plant Pest Risk Assessment for  
Glyphosate-Tolerant Alfalfa Events  
J101 and J163**

## **Plant Pest Risk Assessment for Glyphosate-Tolerant Alfalfa Events J101 and J163**

This plant pest risk assessment is to determine whether glyphosate-tolerant (GT) alfalfa events J101 and J163 are unlikely to pose a plant pest risk. If APHIS determines that a genetically engineered (GE) organism is not a plant pest, APHIS then has no regulatory authority over that organism.

APHIS' authority to regulate genetically engineered organisms under the Plant Protection Act (PPA) (7 U.S.C. Sec 7701 *et seq.*) is limited to those GE organisms that are plant pests as defined under Section 14 of the PPA.

“Plant Pest - The term “plant pest” means any living stage of any of the following that can directly or indirectly injure, cause damage to, or cause disease in any plant or plant product:

- (A) A protozoan.
- (B) A nonhuman animal.
- (C) A parasitic plant.
- (D) A bacterium.
- (E) A fungus.
- (F) A virus or viroid.
- (G) An infectious agent or other pathogen
- (H) Any article similar to or allied with any of the articles specified in the preceding subparagraphs.”

Of the information requested by APHIS for submission of a petition for nonregulated status (§ 340.6(c)(4)), APHIS will use information submitted by the applicant related to plant pest risk characteristics, disease and pest susceptibilities, expression of the gene product, new enzymes, or changes to plant metabolism, weediness of the regulated article, any impacts on the weediness of any other plant with which it can interbreed, and the transfer of genetic information to organisms with which it cannot interbreed. Issues related to agricultural or cultivation practices will be considered in the Environmental Impact Statement for alfalfa events J101 and J163. These two events are not genetically engineered to produce a toxin or pesticide, thus Events J101 and J163 alfalfa are not targeted for use against pests in alfalfa agriculture. Thus, APHIS did not examine the effects of the regulated article on nontarget organisms. However, APHIS does examine the effects of alfalfa events J101 and J163, and potential use of glyphosate on animals, plants, and Threatened and Endangered Species (TES) in the Environmental Impact Statement. APHIS has not identified any issues related to indirect plant pest effects on agricultural production caused by alfalfa events J101 and J163.

Potential impacts to be addressed in this risk assessment are those that pertain to the use of alfalfa events J101 and J163 and their progeny in the absence of confinement. The genetically engineered construct inserted in alfalfa events J101 and J163 was evaluated to determine if those sequences in J101 and J163 cause plant disease. Morphological characteristics of alfalfa events

J101 and J163 were analyzed to determine if these alfalfa varieties would become weedy or invasive. The potential for gene flow to, and introgression of the genetically engineered construct into, other alfalfa varieties or wild relatives of alfalfa were also evaluated to determine the potential of increased weedy or invasive characteristics in other plant species. APHIS also analyzed the propensity of alfalfa events J101 and J163 to become greater reservoirs of plant pests (insects or pathogens) compared to conventional alfalfa varieties, and potential for horizontal gene transfer between alfalfa events J101 and J163 and bacteria.

### **Development of Glyphosate-Tolerant Alfalfa Events J101 and J163**

Alfalfa events J101 and J163 were engineered to be glyphosate-tolerant by inserting a gene into the alfalfa genome that codes for the enzyme 5-enolpyruvylshikimate-3-phosphate synthase (CP4-EPSPS) that continues to function in the presence of glyphosate. The gene is from the common soil bacterium *Agrobacterium* sp. strain CP4 and was introduced into alfalfa via a disarmed *Agrobacterium*-mediated transformation protocol. The management of weeds in alfalfa fields can be an expensive, labor intensive, and sometimes complicated operation. Often farmers use pre-emergent herbicides that will stop some weed seeds from germinating and post-emergent herbicides that will control some weeds after germination. Typically, pre-emergent herbicide use is applied throughout the field because of the assumption that weeds will always be a problem in all parts of the field. Additionally, although these herbicides reduce weeds, most of these herbicides cause temporary damage to the desired alfalfa plants which results in reduced yields. With J101 and J163 and progeny, farmers will have the option of applying herbicide after weeds have germinated to only in the areas of the field where there are weeds, and also apply glyphosate herbicide without substantial damage to the alfalfa plants.

Glyphosate, a broad spectrum systemic herbicide, is one of the most environmentally friendly herbicides commercially available. The glyphosate herbicide (N-phosphonomethyl-glycine) is registered for non-selective weed control on both non-food use and food use plants.

Glyphosate works by interfering with normal plant metabolism by competing with the naturally present enzyme, 5-enolpyruvyl-3-phosphoshikimate acid synthase (EPSPS). EPSPS is involved in the biosynthesis of the aromatic amino acids, phenylalanine, tryptophan, and tyrosine (as well as some secondary metabolites) through the shikimate pathway. These aromatic amino acids are essential building blocks of proteins in all species. As a consequence of interfering with aromatic amino acid biosynthesis, plant cells cannot complete the synthesis of proteins and the plant dies (Kishore and Shah 1988). EPSPS is found naturally in all plants, fungi and some bacteria but is not present in animals (including humans). For animals, aromatic amino acids must be obtained through the diet (Steinrucken and Amrhein 1980). Consequently, all animals are naturally exposed to sources of EPSPS through their normal diets.

### **1. Description of inserted genetic material and potential of the material to cause plant disease.**

Data supplied in the petition and reviewed by APHIS (Section V.A., pp. 38-68) support the conclusion that events J101 and J163 contain the following sequences: (1) a 35S promoter from a modified figwort mosaic virus (P-FMV), (2) coding sequence for a chloroplast transit peptide from *Arabidopsis thaliana*, (3) the 5-enolpyruvylshikimate-3-phosphate synthase gene (*epsps*) from *Agrobacterium* sp. strain CP4, and (4) DNA containing polyadenylation sequences from the

3' non-translated region of the *Pisum sativum* (pea) *rbcS* E9 gene. The non-coding 35S promoter is from the plant pathogen figwort mosaic virus. This sequence, however, cannot cause plant disease and serves a purely regulatory function for the *epsps* gene. The *epsps* gene is from the soil-inhabiting bacterial plant pathogen, *Agrobacterium* sp. strain CP4. It encodes the CP4-EPSPS protein which functions to impart tolerance to the broad spectrum herbicide glyphosate. It does not cause disease and has a history of safe use in a number of deregulated genetically engineered plants (e.g., corn, cotton, soybean, rapeseed, and sugar beet varieties).

The plant material used for development of events J101 and J163 was Forage Genetics International (FGI) proprietary alfalfa clone R2336 from a high yielding, fall dormant breeding population. The initial plants, selected for tolerance to glyphosate, were designated J101 and J163, and various populations were developed from these events to provide the data presented in the petition. Events J101 and J163 were developed using a disarmed (i.e. pathogenicity genes removed) *Agrobacterium*-mediated transformation system of sterile alfalfa seedling cotyledons. Post-transformation, *Agrobacterium* were eliminated from tissues by a 7-week culture on antibiotic-containing medium. Glyphosate was used to select for transformed tissues containing the *epsps* gene construct. This technique using disarmed *Agrobacterium* followed by selection has a 20-year history of safe use and has been used for transformation of a variety of plant species and tissues (Howard *et al.*, 1990).

Data were provided and reviewed by APHIS that demonstrate stable integration and inheritance of the *epsps* gene and its associated regulatory sequences over several breeding generations. Statistical analyses show that glyphosate tolerance is inherited as a dominant trait in a typical Mendelian manner (petition Table V-1, p. 71).

## **2. Potential impacts based on the relative weediness and/or invasiveness of alfalfa events J101 and J163**

APHIS assessed whether alfalfa events J101 and J163 are any more likely to become weeds than the non-transgenic control populations, or other currently cultivated alfalfa. The assessment encompasses a thorough consideration of the basic biology of alfalfa and an evaluation of unique characteristics of alfalfa events J101 and J163.

Almost all definitions of weediness stress as core attributes the undesirable nature of weeds from the point of view of humans; from this core, individual definitions differ in approach and emphasis (Baker, 1965; de Wet and Harlan, 1975; Muenscher, 1980; Booth *et al.*, 2003). The parent plant in this petition, *Medicago sativa* L., is not listed as a serious weed in A *Geographical Atlas of World Weeds* (Holms *et al.*, 1991) or as a weed in *World Weeds: Natural Histories and Distribution* (Holms *et al.*, 1997), *Weeds of the North Central States* ([http://www.aces.uiuc.edu/vista/html\\_pubs/WEEDS/list.html](http://www.aces.uiuc.edu/vista/html_pubs/WEEDS/list.html)), *Weeds of the Northeast* (Uva *et al.*, 1997), or *Weeds of the West* (Whitson *et al.*, 1992). Alfalfa is not listed as a noxious weed species by the U.S. Federal Government (7 CFR Part 360), is not listed as a weed in the major weed references (Crockett 1977; Holm, Pancho *et al.* 1979; Muenscher 1980), nor is it on other weed lists such as: Washington State Weed Lists ([http://www.nwcb.wa.gov/weed\\_list/weed\\_list.htm](http://www.nwcb.wa.gov/weed_list/weed_list.htm)), California Weed Species Lists (<http://www.extendinc.com/weedfreefeed/list-b.htm>), Montana County Noxious Weed

List(<http://agr.mt.gov/weedpest/noxiousweeds.asp> ), and North Dakota Noxious Weeds (<http://www.ext.nodak.edu/extpubs/plantsci/weeds/w1103w.htm> ).

Alfalfa is not considered a serious weed, a noxious weed or an invasive species in the United States, even though feral (free-living) populations are fairly common and volunteers may occur in succeeding crops.

The updated Southern Weed Science Society (SWSS), in collaboration with the North Central Weed Science Society, Interactive Encyclopedia of North American Weeds Version 3.0 (447 entries), includes alfalfa (NCWSS 2005). This is an updated version of the 1998 version cited above. The documentation provided by this list does not indicate why alfalfa is considered a weed. It is possible that it is included because it can be an unwanted volunteer in agricultural settings.

The author of the alfalfa segment of the SWSS Weed Identification guide has stated that alfalfa is not “an invasive weed” nor does it “displace native species,” but alfalfa does colonize disturbed areas (Brett Serviss, Docket No. 04-085-1 #480).

Generally feral populations, many of which are along roadsides, are not a problem, and generally no attempts are made to control these populations. In some instances, these feral populations are considered advantageous and are encouraged (petition Appendix 3, p. 375, 12/31/02 Letter from South Dakota State University). These volunteer plants can be controlled by mechanical means or several other registered herbicides besides glyphosate. Alfalfa possesses few of the characteristics of plants that are notable of successful weeds (Baker, 1965; Keeler, 1989; Booth et al., 2003).

APHIS reviewed various data sets comparing J101 and J163 populations and non-transgenic control populations (petition Section VI pages 99-254) to aid in determining whether the J101 and J163 populations were changed in any manner that might affect the plants ability to persist or compete as a weed and as a method of determining the presence of unintended effects. Data were reviewed on seed dormancy, seed germination, seedling emergence, seedling vigor, spring stand, spring vigor, seed yield, vegetative growth or plant vigor, plant dormancy, growth habit, flowering properties, effect on symbiotic organisms, all characteristics that might relate to or have an effect on increased weediness.

Seed Dormancy: Seed dormancy, which includes hard seed (a water impermeable seed coat (AOSA, 2002)) as found in alfalfa, has a potential effect on weediness by affecting the soil seed bank (the total quantity of viable seeds of various species in the soil at any one time) and allowing the seed to remain viable over various seasons and potentially over several years. The percentage of hard seed in alfalfa can vary in a particular seed lot, depending on genetic factors, environmental conditions during and after seed maturation, and harvesting methods (Bass et al., 1988). The data found in the petition for hard seed (Section VI pages 114-135) is also quite variable. In the first year, seed of J101 and J163 populations had a significantly higher level of hard seed than the control populations. In the second year, the seed in J101 and J163 populations had a significantly lower level of hard seed than the control populations. In the third year, the seed of J101 and J163 populations were both higher and lower levels of hard seed than the

control populations with the mean of the J101 and J163 populations being essentially equal to the control populations. In addition, during the public comment period in late 2004 and early 2005 after notifying the public of the availability of the petition 04-110-01p for deregulation and the corresponding environmental assessment, six scientists from four different states each with more than 20 years experience working with alfalfa and or seed physiology commented that there was no evidence linking the increased levels of hard seed with glyphosate tolerance. They also generally noted that hard seed in the case of alfalfa was not linked to dormancy since their observations and studies in the past showed that hard seed almost always germinated within a few weeks of seeding and the seedlings that developed were generally too weak and noncompetitive to survive. From the data submitted in the petition and from the comments from these scientists, APHIS concludes that glyphosate tolerance does not cause increased seed dormancy.

Seed Germination: The level of alfalfa seed germination as determined under laboratory conditions is generally negatively correlated to the level of hard seed since both are determined in the same seed test (AOSA 2002). If the percentage of hard seed is determined to be high in the seed test, then the percentage of seed germination is generally lower. If the percentage of hard seed is low, then the percentage of seed germination is generally higher. Increased levels of seed germination may have an effect on weediness by allowing more plants to establish in the environment by outnumbering plants with lower levels of germination. The data in the petition for seed germination (Section VI pages 114-135) are best explained by the levels of hard seed in the various samples of seed tested for each of the populations of J101, J163, control and representative varieties. From the data submitted in the petition, APHIS concludes that glyphosate tolerance does not cause increased seed germination.

Seedling Emergence: Increased seedling emergence may have an effect on weediness by allowing more plants to establish in the environment by outnumbering plants with lower levels of seedling emergence. Seedling emergence is a combination of seed germination rate, seed dormancy which may decrease the number of seeds germinating, and the effect of various environmental conditions on the germinating process such as cold soils, level of available water, insect predation, and level of disease pressure on the germinating seeds. Therefore seedling emergence is an overall score for the level of plant survival between seeds planted and surviving seedlings. The data in the petition for seedling emergence (Section VI pages 135-157) indicate that J101 and J163 populations were essentially the same as the control populations or reference varieties. From the data submitted in the petition, APHIS concludes that glyphosate tolerance does not cause increased seedling emergence,

Seedling Vigor: Increased seedling vigor may have an effect on weediness by allowing more seedling plants to establish in the environment by outnumbering and outcompeting plants with lower levels of seedling vigor. Increased seedling vigor is a combination of early seedling establishment, increased vigorous seedling growth, and tolerance to seedling diseases. The data in the petition for seedling vigor (Section VI pages 135-157) indicate that J101 and J163 populations were essentially the same as the control populations or reference varieties. From the data submitted in the petition, APHIS concludes that glyphosate tolerance does not cause increased seedling vigor.

Spring Stand: This is a rating for winter survival or winter hardiness. Higher ratings for spring stand would indicate better winter survival. Increased spring stand may have an effect on weediness by outcompeting other more desirable plants allowing more plants to survive and compete in the environment to the detriment of other plants. The data in the petition for spring stand (Section VI pages 135-157) indicate that J101 and J163 populations were essentially the same as the control populations or reference varieties. From the data submitted in the petition, APHIS concludes that glyphosate tolerance does not cause increased spring stand.

Spring Vigor: This trait could be considered a combination of spring stand and the rate of plant growth in the spring. A dense spring stand along with rapid spring plant growth would be very detrimental for the growth of other plant species. Dense alfalfa stands are known to be very competitive against weeds. On the other hand the argument could be made that an alfalfa variety that has an increased ability to provide a denser spring stand along with excellent spring vigor could be considered more weedy if allowed to grow in an area where it is not wanted. The data in the petition for spring vigor (Section VI pages 135-157) indicate that J101 and J163 populations were essentially the same as the control populations or reference varieties. From the data submitted in the petition, APHIS concludes that glyphosate tolerance does not cause increased spring vigor.

Seed Yield: High seed yield is a desirable characteristic of a successful commercial alfalfa variety since seed yield is a major component in the final selling price. Higher seed yields (weight per acre) generally translate into lower selling prices if all other factors are held constant. On the other hand, the argument could be made that an alfalfa variety that has a higher seed yield could be considered more weedy if allowed to grow in an area where it is not wanted. Higher seed yield would mean more seeds and or bigger seeds would be produced that could give it a selective advantage. The seed yield data in the petition provided information on seed weight per 1000 pollinations, seed weight per plant, weight per seed, and the number of seeds per flower (Section VI pages 209-217) for the J101 and J163 populations and the control populations or reference varieties. From the data submitted in the petition, APHIS concludes that glyphosate tolerance does not cause increased seed yield.

Vegetative Growth or Plant Vigor: High forage yield is a desirable characteristic of a successful alfalfa variety since a high yield of highly nutritious forage is the goal of forage production for animal consumption. Good plant vigor is also necessary for minimizing weed competition in a forage field. More vegetative growth or more plant vigor could also be considered a characteristic that could lead to more weediness. The petition provided information on vegetative growth or plant vigor in the form of forage yield (fresh weight per acre or weight per plant), crop growth stage (Mean Stage by Count), regrowth after cutting, and growth and or vigor scores (Section VI pages 135-137, 167-170, 175-182) , for the J101 and J163 populations and the control populations or reference varieties. A significantly higher forage yield for one or more cuttings or total weight for the year could possibly indicate a faster growing or larger plant that in the right environment could indicate more weediness. A significantly higher crop stage growth rating would indicate that more plants could be producing seeds more rapidly which also could mean more weediness. A significantly higher rating for regrowth after cutting could possibly indicate that the plants are more vigorous after cutting or grazing, possibly making these plants more competitive against other plants. Growth and or vigor scores that are consistently

and significantly higher over dates within a year, over years and over locations could also possibly provide information on the potential competitiveness of a plant which may make it more weedy. From the data submitted in the petition, no significant consistent pattern was noted for higher forage yield, for higher crop stage growth rating, for higher regrowth rating, or for higher growth and vigor scores. Thus APHIS concludes that glyphosate tolerance does not cause increased vegetative growth or plant vigor.

Plant Dormancy: This characteristic and its relationship to possible weediness is highly dependent on the climate in which the plant is grown. More plant dormancy is critical for the perennial plant's survival in climates with freezing winter temperatures. A plant that is actively growing when freezing temperatures occur will generally die. On the other hand, if the plant has a high level of dormancy going into the fall of the year (the plant slows or stops active growth and the various physiological properties are conditioning the plant for withstanding freezing temperatures) and the plant is growing in a climate with no freezing winter temperatures, the plant is at a competitive disadvantage to those plants that are actively growing. Alfalfa varieties vary widely in dormancy from no hardiness to high levels of dormancy. In the petition, fall dormancy was determined by plant height measured in the fall after the last cutting of the season or as a visual rating. Greater fall plant height and higher visual ratings would indicate greater fall dormancy. From the data submitted in the petition (Section VI pages 135-157, 175-182), no significant differences were noted for fall plant height or visual fall dormancy ratings. Thus, APHIS concludes that glyphosate tolerance does not change fall dormancy.

Growth Habit: A prostrate growth habit or an upright growth habit is not necessarily weediness characteristics in themselves but more a relationship to the plant community in which they are growing. A rapidly growing plant with a prostrate growth habit would be more competitive against plants that are slow to germinate or slow to regrow in the spring or after grazing. A rapidly growing plant with an upright growth habit would be more competitive in a more dense stand of plants slow to germinate or slow to regrow in the spring or after grazing. From the data submitted in the petition (Section VI pages 135-137, 158, 175-182), no significant differences were noted for fall growth habit. Therefore, APHIS concludes that glyphosate tolerance does not change fall growth habit.

Survival: For a perennial crop, survival is an important characteristic since it helps determine the economically viable time length of commercial fields. If the alfalfa forage fields can survive longer, the significant costs involved with establishing and destroying fields can be avoided for longer periods of time and prorated over more harvests. It is a measure of a variety's tolerance of various biotic and abiotic stress, such as frequent mowing/grazing, freezing temperatures, diseases, insects, traffic from vehicles and animals, etc. The possibility exists that if an alfalfa plant can survive longer when stressed by the same biotic and abiotic factors, then it may have a greater potential to become weedy in some circumstances. From the data submitted in the petition (Section VI pages 175-182), no significant differences were noted for survival, and APHIS concludes that glyphosate tolerance does not change survival.

Flower and Pollen Morphology: For alfalfa that is dependent on bees for cross pollination and seed production, changes in flower morphology may have an effect on bee visitation. Exactly

how changes in flower morphology may affect weediness are not understood, so if any changes are noted then it needs to be examined more closely. Data submitted in the petition (Section VI pages 183-209) provided measurements on number of flowers per raceme, length of the standard petal, length of the keel petal, diameter of the calyx tube, length of the sexual column, number of pollen grains per flower, percent pollen germination, percent pollen viability, pollen diameter, and visual observation of the following: flower color, general flower morphology, rachis attachment to the stem, flower attachment to the rachis, flower ripening pattern of the raceme, general observation of the pollen load per flower, self fertility of flowers whether tripped without any assistance or mechanically tripped by the researcher, and general seed morphology. From these data submitted in the petition, no significant differences were noted for any of these flower and pollen characteristics. Therefore, APHIS concludes that glyphosate tolerance does not change flower and pollen characteristics and therefore cannot have an effect on weediness.

Symbiotic Organisms: Since nitrogen-fixing bacteria (*Sinorhizobium meliloti*, formerly known as *Rhizobium meliloti*) are known to have a symbiotic relationship with legumes, observations were taken on nodule formation (Section VI pages 248-251) as well as phenotypic observations that would be affected by modification of the nitrogen fixing process, such as seedling growth (Section VI pages 248-251), levels of total protein, asparagine, and aspartate (Section VI pages 223-247), and forage yield (Section VI pages 135-137, 167-170, 175-182). From these data submitted in the petition, no significant differences were noted for any of these symbiotic nitrogen fixing relationships. Thus, APHIS concludes that the glyphosate tolerance trait does not effect symbiotic relationships and therefore cannot have an effect on weediness.

No unusual characteristics were noted that would suggest increased weediness of J101 and J163 plants. Additionally, no characteristics relating to disease or insect resistance that might affect weediness were noted. These characteristics were consistent over all field trial locations (petition Tables VI-16, VI-18, VI-19, VI-20 pages 159-175). J101 and J163 alfalfa plants are still susceptible to the typical insect and disease pests of alfalfa. Therefore, there is no selective advantage to alfalfa containing CP4-EPSPS compared to conventional alfalfa, and there is no increased potential for weediness or invasiveness from alfalfa events J101 and J163.

### **3. Potential impacts from gene flow and gene introgression from alfalfa events J101 and J163 into its sexually-compatible relatives.**

APHIS evaluated the potential for hybridization and gene introgression to occur from alfalfa events J101 and J163 to sexually compatible wild (free-living) relatives, and considered whether such introgression would result in increased weediness. Alfalfa is sexually compatible with several subspecies within the *M. sativa* complex (Small and Jomphe, 1989). The center of origin for the genus *Medicago* is generally believed to be in the Caucasus, northwestern Iran and northeastern Turkey; the genus is not native in North America. An additional 18 *Medicago* species are known to be naturalized (free-living) or possibly so within the United States, of which only *M. lupulina* (black medic) is widely naturalized throughout the United States. None of these species are native to the United States, and none are sexually compatible with *M. sativa*. The *M. sativa* complex, which was introduced into North America early by Europeans for forage and includes all the commercial alfalfa varieties, is a group of closely related subspecies, including the cultivated *M. sativa* ssp. *sativa* and *M. sativa* ssp. *falcata* (synonym *M. falcata*) (Small and Jomphe, 1989).

In addition to the *M. sativa* complex within which all of the subspecies are sexually compatible to some degree, an additional 17 and possibly 18 *Medicago* species have been recognized as being naturalized (free-living) or possibly so in the United States (USDA-NRCS, 2004; Kartesz, 2004). All of these 18 species are annual species, except for the species *M. hybrida* (in *Medicago* section *Medicago*) hybrids of which have only been produced experimentally by embryo culture. No annual species are known to hybridize with *M. sativa* (Quiros and Bauchan, 1988; McCoy and Bingham, 1988; and the petition's Appendix 4).

*Medicago lupulina* (black medic) is the species that might be of most concern within this list of 18 species. It is considered a weed in lawns and waste places and in forages since its seeds frequently contaminate forage legume seed crops. Black medic is an annual (possibly sometimes short-lived perennial) self-pollinating species and is known to occur throughout the United States. Successful hybridizations between *M. sativa* and *M. lupulina* have been reported (Southworth, 1928; Fryer, 1930; Shrock, 1943). However, because of the lack of hybrids after many subsequent experiments, there is general agreement that these putative "hybrids" were most likely not hybrids but due to self-fertilization (Lesins and Gillies, 1972; Fridriksson and Bolton, 1963; Valizadeh et al., 1996). For more details on this topic, see Section E.1 (p. 284) and Appendix 4 of the petition. Based on all the recent data available on this subject, APHIS' opinion is that hybridization between *Medicago sativa* and *M. lupulina* has an extremely low to non-existent probability of occurring in a non-experimental or even in an experimental setting.

APHIS concludes that the potential of the glyphosate tolerance trait moving from J101 and J163 to other sexually compatible *Medicago* species in the United States is essentially non-existent.

#### **4. Potential of alfalfa events J101 and J163 to harbor plant pests (insects and disease)**

The data submitted by Monsanto and FGI indicated no significant differences between alfalfa events J101 and J163 and the non-transgenic counterparts for disease observations (as measured by seedling damping-off (e.g., fungal genera such as *Pythium*, *Phytophthora*, *Aphanomyces*); foliar diseases (e.g., fungal genera such as *Leptosphaerulina*, *Colletotrichum*, *Peronospora*, *Phoma*, *Stemphylium*, *Cercospora*, and stem nematodes like *Ditylenchus*); and root rots, vascular wilts and crown diseases (e.g., fungal genera such as *Phytophthora*, *Verticillium*, *Fusarium*, *Phoma*, and bacterial wilt caused by *Clavibacter*) and pest susceptibility (as measured by potato leafhoppers (*Empoasca fabae*), aphids [pea (*Acyrtosiphon pisum*), blue (*A. kondoi*) and spotted alfalfa aphids (*Therioaphis maculata*)], alfalfa weevil (*Hypera postica*), lygus bugs (*Lygus* species), other plant bug species (family *Miridae*) and alfalfa caterpillars (various lepidopteran species)) (Tables VI-16, VI-18 to VI-20 of petition pages 159-175). The data presented in the petition indicates no difference in compositional and nutritional quality of alfalfa events J101 and J163 compared to conventional alfalfa, apart from the presence of CP4-EPSPS. Although some of the variables measured by the applicant showed statistically significant differences between alfalfa events J101 and J163 and the nontransgenic control population (Tables VI-34 and VI-35 of the petition, pages 226-244), none of the values for the forage composition characteristics were outside the range of natural variability of conventional alfalfa as found in the literature (Table VI-36 of the petition, page 245). Therefore, the composition of alfalfa events

J101 and J163 is not biologically different than conventional alfalfa, and the events are thus susceptible to the same pest population as conventional alfalfa. Additionally, alfalfa events J101 and J163 are similarly affected by typical plant diseases found in alfalfa, and do not harbor an altered pest or pathogen community compared to other alfalfa varieties.

## **5. Transfer of genetic information to organisms with which it cannot interbreed**

Horizontal gene transfer and expression of DNA from a plant species to bacteria is unlikely to occur. First, many genomes (or parts thereof) have been sequenced from bacteria that are closely associated with plants including *Agrobacterium* and *Rhizobium* (Kaneko et al. 2000, Wood et al. 2001, Kaneko et al. 2002). There is no evidence that these organisms contain genes derived from plants. Second, in cases where review of sequence data implied that horizontal gene transfer occurred, these events are inferred to occur on an evolutionary time scale on the order of millions of years (Koonin et al. 2001, Brown 2003). Third, transgene DNA promoters and coding sequences are optimized for plant expression, not prokaryotic bacterial expression. Thus even if horizontal gene transfer occurred, proteins corresponding to the transgenes are not likely to be produced. Fourth, the Food and Drug Administration (FDA) has evaluated horizontal gene transfer from the use of antibiotic resistance marker genes. The FDA concluded that the likelihood of transfer of antibiotic resistance genes from plant genomes to microorganisms in the gastrointestinal tract of humans or animals, or in the environment, is remote (<http://vm.cfsan.fda.gov/~dms/opa-armg.html>). Therefore APHIS concludes that horizontal gene transfer is unlikely to occur and thus poses no significant environmental or plant pest risk.

## **Conclusion**

APHIS has reviewed and conducted a plant pest risk assessment on alfalfa events J101 and J163 alfalfa. Due to the lack of plant pest risk from the inserted genetic material, the lack of weediness characteristics of alfalfa events J101 and J163 alfalfa, the lack of atypical responses to disease or plant pests in the field, the lack of deleterious effects on non-targets or beneficial organisms in the agro-ecosystem, and the lack of horizontal gene transfer, APHIS concludes that Events J101 and J163 alfalfa are unlikely to pose a plant pest risk.

Alfalfa events J101 and J163 are also not plant pests as defined by the PPA. Neither alfalfa events J101 or J163, nor the EPSPS enzyme engineered into the alfalfa events, are any of the organisms listed in the statutory definition of a plant pest. Enzymes such as EPSPS are proteins that catalyze chemical reactions. Enzymes are not “living,” nor a “living stage” of any of the organisms (“articles”) listed in the PPA’s definition of a plant pest in subsections A-G of 7 U.S.C. 7702(14). Likewise, the EPSPS enzyme within alfalfa events J101 and J163 also does not fall within the statutory definition of a plant pest as listed in subsection ‘(H)’ of the PPA’s plant pest definition in 7 U.S.C. 7702(14).

An “article” as defined in the PPA at 7 U.S.C. 7702(1) is a “material or tangible object that could harbor plant pests.” In order to meet the PPA’s definition of a plant pest, the EPSPS enzyme in these alfalfa events would have to be **both** a living stage of one of the organisms (articles) listed in subsections A-G and would also have to be able to harbor a plant pest. However, an enzyme is not a living stage of one of the organisms (articles) listed in subsections A-G. Moreover, because enzymes are non-living, sub-cellular components of living cells, they are not of the scale

to “harbor” another living organism. Therefore, an enzyme (including the EPSPS enzyme in the alfalfa events J101 and J163) does not fall within the PPA’s definition of a plant pest.

Alfalfa events J101 and J163 also are clearly not living stages of any of the organisms (articles) listed in subsections A-G of 7 U.S.C. 7702(14). Nor are alfalfa events J101 and J163 a living stage of any article (organism) similar to or allied with any of the articles specified in subsections A-G as required by subsection H of 7 U.S.C. 7702(14). Thus, alfalfa events J101 and J163 are not plant pests as defined by the PPA.

APHIS has determined that neither the alfalfa events J101 and J163, nor the EPSPS enzyme in these GT alfalfa events, are a “living stage” of any of the organisms (articles) listed in subsections A-H of the PPA’s plant pest definition. Moreover, neither the alfalfa events J101 and J163, nor the EPSPS enzyme in GT alfalfa is an article that harbors plant pests.
